Supporting Information

ABSTRACT: A theoretical study was elaborated to support the experimental results of the Zn-doped \(\alpha-\text{Ag}_2\text{WO}_4\). Theses \(\alpha-\text{Ag}_{2-2x}\text{Zn}_x\text{WO}_4\ (0 \leq x \leq 0.25)\) solid solutions were obtained by coprecipitation method. X-ray diffraction data indicated that all \(\alpha-\text{Ag}_{2-2x}\text{Zn}_x\text{WO}_4\ (0 \leq x \leq 0.25)\) microcrystals presented an orthorhombic structure. The experimental values of the micro-Raman frequencies were in reasonable agreement with both previously reported and calculated results. Microscopy images showed that the replacement of \(\text{Ag}^+\) by \(\text{Zn}^{2+}\) promoted a reduction in the average crystal size and modifications in the morphology, from rod-like with hexagonal shape to roll-like with a curved surface. A theoretical methodology based on the surfaces calculations and Wulff constructions was applied to study the particle shapes transformations and the surface energy variations in \(\alpha-\text{Ag}_{2-2x}\text{Zn}_x\text{WO}_4\ (0 \leq x \leq 0.25)\) system. The decrease in the band gap value (from 3.18 to 3.08 eV) and the red shift in photoluminescence with the \(\text{Zn}^{2+}\) addition were associated with intermediary energy levels between the valence and conduction bands. First-principles calculations with density functional theory associated with B3LYP hybrid functional were conducted. The calculated band structures revealed an indirect band gap for the \(\alpha-\text{Ag}_{2-2x}\text{Zn}_x\text{WO}_4\) models. The electronic properties of \(\alpha-\text{Ag}_2\text{WO}_4\) and \(\alpha-\text{Ag}_{2-2x}\text{Zn}_x\text{WO}_4\) microcrystals were linked to distortion effects and oxygen vacancies \((V_0)\) present in the clusters, respectively. Finally, photoluminescence properties of \(\alpha-\text{Ag}_2\text{WO}_4\) and \(\alpha-\text{Ag}_{2-2x}\text{Zn}_x\text{WO}_4\) microcrystals were explained by means of distortional effects and oxygen vacancies \((V_0)\) in \([\text{Ag}_2\text{O}_y]\) \((y = 2, 4, 6, 7)\) and \([\text{WO}_6]\) clusters, respectively, causing a red shift. Calculations revealed that the substitution for \(\text{Ag}^+\) with \(\text{Zn}^{2+}\) occurred randomly in the \(\alpha-\text{Ag}_2\text{WO}_4\) lattice, and it was more favorable on the \text{Ag}^4 site, where the local coordination of \text{Ag}^2 cations was four.

1. INTRODUCTION

Metal tungstates are a well-known family of inorganic materials due to their prominent properties with multifunctional applications in many fields such as catalysis, photocatalysis, microbial agents, and luminescence.\(^{1-12}\)

\(\alpha-\text{Ag}_2\text{WO}_4\) is a significant member of this family, and a variety of characteristic properties and behaviors have been obtained using different methods such as electrochemical\(^{13}\) sonochemical,\(^{3,14}\) supersonic assisted homogeneous precipitation,\(^{15}\) conventional hydrothermal\(^3\) hydrothermal microwave,\(^5,16-21\) and coprecipitation method.\(^3,4,16,22-30\) Very recently, Fan et al. reported a preparation method for highly uniform one-dimensional \(\alpha-\text{Ag}_2\text{WO}_4\) nanostructures with a controllable aspect ratio.\(^{31}\) \(\alpha-\text{Ag}_2\text{WO}_4\) has received significant attention owing to its potential applications, in different fields such as organic catalysis,\(^{24,32,33}\) photocatalysis,\(^4,17,34\) electrocatalysis,\(^25\) gas sensing,\(^1,19\) dye adsorbents,\(^14\) photoswitches,\(^35\) and as antimicrobial\(^2\) and antibacterial agents.\(^{14,15,17}\) These unique features provide the opportunity to tailor the basic physical and chemical properties and performance of \(\alpha-\text{Ag}_2\text{WO}_4\) compounds by intentionally mixing them with metals.

Obtaining solid solutions, formed by a mixture of two or more crystalline solids, is found to be a very effective strategy to tailor the crystal structure, continuous tenability of band gap values, and optical properties. Solid solutions may have new properties or improve on those existing in separate phases. In particular, the synthesis and formation mechanisms of the solid solutions of metal tungstate, their stability and corresponding properties, as well as the potential technological applications, are important topics of research.

In this context, the synthesis and characterization of solid solutions involving metal tungstates such as \(\text{Sr}_{1-x}\text{Pb}_x\text{WO}_4\)\(^{36}\) \(\text{Ca}_{1-x}\text{Sr}_x\text{WO}_4\)\(^{37}\) \(\text{Ba}_{1-x}\text{Sr}_x\text{WO}_4\)\(^{38}\) and \(\text{Sr}_{1-x}\text{Ba}_x\text{WO}_4\)\(^{35}\) have been performed. The photoluminescence (PL) properties of \(\text{Ca}_{1-x}\text{Sr}_x\text{WO}_4\)\(^{39}\) and \(\text{Ca}_{1-x}\text{Cd}_x\text{WO}_4\)\(^{40}\) have been analyzed,

while the structures, optical properties, and magnetism have been studied for $\text{Zn}_{1-x}\text{NiWO}_4$\textsuperscript{41} Mn$_{1-y}\text{CuWO}_4$\textsuperscript{42} Cd$_{1-x}\text{ZnWO}_4$\textsuperscript{43} Ni$_{1-x}\text{CoWO}_4$\textsuperscript{44} Zn$_{1-x}\text{CuWO}_4$\textsuperscript{45} and Zn$_{1-x}\text{CoWO}_4$\textsuperscript{46}.

Our group is engaged in a research devoted to finding a rational synthesis of solid based on the $\alpha$-Ag$_2$WO$_4$ material, and very recently, we performed a study on the effects of chemical substitution of $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ solid solutions.\textsuperscript{47} $\alpha$-Ag$_2$WO$_4$ presents an orthorhombic structure with space group $Pn\text{2}n\text{2}$. Each W cation is bonded to six oxygen atoms, while the Ag cations are found to have two-, four-, six-, and seven-coordinated geometries. Therefore, the corresponding building blocks of this structure are the $[\text{WO}_6]$ cluster with $O_h$ symmetry and $[\text{AgO}_4]$ ($y = 2, 4, 6, 7$) clusters with $C_{2v}$ $T_d\theta$ $O_h$ and $D_4h$ symmetries, respectively. These clusters are distorted, but different $W$–O and $Ag$–O distances can be sensed, and then these clusters present deviations from the ideal symmetry.\textsuperscript{48} $\text{ZnWO}_4$ has a monoclinic structure with the space group $P2_1/c$, where six oxygen ions are arranged around $W$ and $Zn$ cations forming a distorted octahedral coordination, corresponding to $[\text{WO}_6]$ and $[\text{ZnO}_6]$ clusters, respectively.\textsuperscript{49} In both $\alpha$-Ag$_2$WO$_4$ and $\text{ZnWO}_4$ structures, all clusters are asymmetric and not homogeneous. This fact results in a set of nonequivalent clusters of metal–oxygen bonds distributed over the lattice. In addition, differences in the ionic radii and charges between $Ag^+$ and $Zn^{2+}$ may produce lattice distortions and vacancies in the crystal. Thus, through the substitution of $Ag^+$ with $Zn^{2+}$ in $\alpha$-Ag$_2$WO$_4$, an interesting prospect for applications is the control of material properties in the corresponding solid solution by disturbance of the local $M$–O environment.

Herein, we developed new $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ ($0 \leq x \leq 0.25$) solid solutions via a simple coprecipitation (CP) method. The structure was confirmed by X-ray diffraction (XRD), X-ray fluorescence spectroscopy (XRF), Rietveld refinement data, micro-Raman (MR) and Fourier transform infrared (FTIR) spectroscopies. The optical properties were investigated by ultraviolet–visible (UV–vis) diffuse reflectance spectroscopy and photoluminescence (PL). Field-emission scanning electron microscopy (FE-SEM) images were employed to evaluate the shapes, sizes, and growth processes of the crystals as the doped concentration of $\text{Zn}^{2+}$ ions in the $\alpha$-Ag$_2$WO$_4$ network was increased. To complement these experimental results, theoretical calculations with the density functional theory (DFT) were performed. The electronic information, such as band structure and density of states (DOS), and Raman spectra were calculated to understand the phenomenon of structural order–disorder in the $\alpha$-Ag$_2$WO$_4$ structure caused by $\text{Zn}^{2+}$ replacement.

The paper is organized in three other sections. Section 2 describes the methodology details. Section 3 exposes the results and the discussion concerning the structural and properties characteristics. The paper combined experimental and theoretical results in order to understand the relationship between the structural modifications and the obtained PL properties. Section 4 describes our conclusions.

2. EXPERIMENTAL SECTION

Synthesis of $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ Microcrystals. The $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ ($x = 0, 0.05, 0.10, 0.15, 0.20$ and $0.25$) microcrystals were prepared by the CP method. The procedure for the typical $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ microcrystals synthesized by the CP method is described as follows: $1 \times 10^{-3}$ mol of tungstate (VI) sodium dihydrated ($\text{Na}_2\text{WO}_4\cdot2\text{H}_2\text{O}$; 99.5% purity, Sigma-Aldrich) and $2 \times 10^{-3}$ mol of silver(I) nitrate ($\text{AgNO}_3$; 99.8% purity, Sigma-Aldrich) were dissolved separately in 50 mL of deionized water at 80 °C under magnetic stirring. The solution with $Ag^+$ and $\text{NO}_3^-$ was added to the solution containing the $\text{WO}_4^{2-}$ ions, and this solution remained at 80 °C under magnetic stirring for 30 min. After that, a yellow suspension appeared, and a white precipitate was rapidly formed. The solid solutions were prepared according to the molar ratio in $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ ($x = 0.05, 0.10, 0.15, 0.20$, and 0.25) considering the charge balance between $Ag^+$ and $Zn^{2+}$. Zinc nitrate octahydrated ($\text{Zn(NO}_3)_2\cdot8\text{H}_2\text{O}$; 99.99% purity, Sigma-Aldrich) was added to $\text{AgNO}_3$ solution, and the procedure was similar to that described for the $\alpha$-Ag$_2$WO$_4$. The resulting suspensions were washed several times with deionized water to remove the residual $\text{Na}^+$ ions. The crystalline $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ microcrystals were collected and dried in an oven at 70 °C.

Characterization. These $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ microcrystals were structurally characterized by XRD patterns using a D/Max-2000PC diffractometer Rigaku (Japan) with Cu Ka radiation ($\lambda = 1.5406\ \text{Å}$) in the $2\theta$ range from $10^\circ$ to $70^\circ$ in the normal routine with a scanning velocity of $2^\circ$/min and from $10^\circ$ to $110^\circ$ with a scanning velocity of $1^\circ$/min in the Rietveld routine. XRF analyses were performed on a Shimadzu EDX 720 XRF spectrometer. MR spectroscopy was conducted on a Horiba Jobin-Yvon (Japan) spectrometer charge-coupled device detector and argon-ion laser (Melles Griot, United States) operating at $154.5\text{ nm}$ with maximum power of $200\text{ mW}$. The spectra were measured in the range of $230^-1000\text{ cm}^-1$. FTIR spectroscopy was recorded in the range from 250 to $1000\text{ cm}^-1$ using KBr pellets as a reference in a Bomem–Michelson spectrophotometer in transmission mode (model MB102). The shapes and sizes of these $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ microcrystals were observed with an FE-SEM Inspector F50 (FEI Company, Hillsboro, OR) operated at 5 kV. The optical properties of the $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ microcrystals were analyzed by UV–vis and PL spectroscopies. UV–vis spectra were taken using a (Varian, USA) spectrophotometer (model Cary 5G) in a diffuse-reflectance mode. PL measurements were performed through a Monospec 27 monochromator (Thermal Jarrel Ash) coupled to a R446 photomultiplier (Hamamatsu Photonics, Japan). A krypton-ion laser (Coherent Innova 90K; $\lambda = 357.0\text{ nm}$) was used as the excitation source; its maximum output power was maintained at $500\text{ mW}$. The laser beam was passed through an optical chopper, and its maximum power on the sample was maintained at $40\text{ mW}$. PL measurements were performed at room temperature.

Computational Details. All theoretical calculations for the $\alpha$-Ag$_2$WO$_4$ and $\alpha$-Ag$_{2-x}\text{ZnWO}_4$ structure were performed with the CRYSTAL14 software package.\textsuperscript{50} This code uses a Gaussian-type-like basis set to represent crystalline orbitals as a linear combination of Bloch functions defined in terms of local functions (atomic orbitals). The computational method is based in the DFT associated with the Becke’s three-parameter hybrid nonlocal exchange functional\textsuperscript{51} combined with a Lee–Yang–Parr gradient-corrected correlation functional (B3LYP). The diagonalization of the Fock matrix was performed using a $(4 \times 4 \times 4)$ Pack-Monkhorst $k$-points grid in the reciprocal-space. The thresholds controlling the accuracy of the calculation of the Coulomb and exchange integrals were set to $1 \times 10^{-6}$ and $1 \times 10^{-14}$, and the percent of Fock–Kohn–Sham matrix mixing was set to 30 (IPMIX keyword). The lattice parameters and the internal atomic coordinates were fully optimized until all force components were less than $1 \times 10^{-6}\text{ eV Å}^-2$. The basis sets to describe the atomic centers of $\alpha$-Ag$_2$WO$_4$ were the same as those employed by Longo et al.;\textsuperscript{52} $\text{Zn}$ atoms were described by $86^-411d31G$, which was obtained from the Crystal Web site.\textsuperscript{53} The Raman vibrational modes and their corresponding frequencies were calculated using numerical second derivatives of total energies as implemented in the CRYSTAL14 package.\textsuperscript{54} The band structure and DOS of the models were constructed along the appropriate high-symmetry directions of the corresponding irreducible Brillouin zone. Three models were constructed to more accurately describe structural and electronic properties derived from the experimental synthesis, a pure $\alpha$-Ag$_2$WO$_4$ and two models in which the $\text{Zn}^{2+}$ cation substitutes the $Ag^+$ cation.
with formation of Ag vacancy, to consider the charge balance between Ag\(^{+}\) and Zn\(^{2+}\) cations. To evaluate the stability of substituted structures, we directly compared the total energies of the Zn replacement in the \(\alpha\)-Ag\(_{2}\)WO\(_{4}\) structure by direct nondestructive method. The results show that the molar amounts were close to the calculated values for the syntheses. Some small deviations observed between theoretical and experimental values are assigned to matrix effects and equipment errors, such as calibration curve and interference effects.

### Rietveld Refinement Analysis

A detailed study of the XRD patterns was conducted by means of Rietveld refinement analysis using the General Structure Analysis System (GSAS) program.\(^{58}\) This technique allows an estimation of real structure parameters comparing the XRD peak profiles with the profile of other reported papers.\(^{59}\) In these analyses, the background was refined using a Chebyshev polynomial of the first kind, and the peak profiles were adjusted by the Thompson-Cox-Hastings pseudo-Voigt \(\text{pV} - \text{TCH}\)\(^{60}\) function with the asymmetry function described by Finger et al.\(^{61}\) The anisotropy in half-width was taken into account using the model developed by Stephens.\(^{62}\)

In this paper, we performed the Rietveld refinement to check the effects of the substitution of Ag\(^{+}\) by Zn\(^{2+}\) in the crystalline structure of \(\alpha\)-AgWO\(_{4}\). Rietveld refinement plots of \(\alpha\)-Ag\(_{2-x}\)Zn\(_{x}\)WO\(_{4}\) for \((x = 0, 0.05, 0.10, 0.15, 0.20, \text{ and } 0.25)\) respectively, are shown in Figure SI-3. The Rietveld results were in accordance with ICSD Card No. 4165.\(^{55}\) The crystals exhibited a single phase, confirming that there is a substitution for Ag\(^{+}\) by Zn\(^{2+}\) cations in all samples \((x = 0.05, 0.10, 0.15, 0.20, \text{ and } 0.25)\). Figure SI-3a–f shows good concordance between the experimental XRD patterns and theoretical results. This affirmation is based on the slight differences between the experimental intensity \((Y_{\text{Exp}})\) and the calculated intensity \((Y_{\text{Calc}})\), as shown by the line \(Y_{\text{Exp}} - Y_{\text{Calc}}\).

So, the quality of the refinement is generally checked using \(R\)-values, suggesting that the refinement result presents acceptable values. Additional information concerning the refinement reliability and the cell information are illustrated in Table SI-2. On the basis of the Rietveld refinement, there is a small difference between the unit cell parameters of each sample. The volume of the unit cell decreased with the Zn\(^{2+}\) incorporation; this is a consequence of the decrease in the cell parameters (see Table SI-2). Therefore, the substitution process of Ag\(^{+}\) by Zn\(^{2+}\) provokes a rearrangement of the geometry for the \([\text{AgO}_{4}]\) by \([\text{ZnO}_{4}]\) \((y = 2, 4, 6, \text{ and } 7)\) clusters; then, the local geometry of the metals (W, Ag, and Zn) and their corresponding interactions with oxygen anions contribute to the structural and electronic modifications.

### Unit Cell Representation for \(\alpha\)-Ag\(_{2-x}\)Zn\(_{x}\)WO\(_{4}\)

Figure 2 displays a schematic representation of the \(\alpha\)-Ag\(_{1.50}\)Zn\(_{0.25}\)WO\(_{4}\) orthorhombic unit cell. This structure was modeled using the Visualization for Electronic and Structural Analysis (VESTA) program.\(^{63}\) From the lattice parameters and atomic coordinates obtained through of the Rietveld refinements (listed in Table SI-4), it was possible to construct the unit cell represented in Figure 2.
It is well-known\textsuperscript{3,23,47} that $\alpha$-Ag$_3$WO$_4$ is composed of three different W sites (W1, W2, and W3), all coordinated with six oxygen atoms forming a distorted $[\text{WO}_6]$ cluster with an octahedral configuration. Six types of Ag sites with four different coordinations are presented (see Table 1): the Ag1 and Ag2 atoms are bonded with seven oxygen atoms generating a distorted bipyramidal $[\text{AgO}_7]$ clusters; already the Ag3 atoms are linked by six oxygen atoms that form the distorted octahedral $[\text{AgO}_6]$ cluster; for Ag4 and Ag5 atoms are arranged with four oxygen atoms, forming the distorted tetrahedral $[\text{AgO}_4]$ clusters; and finally the Ag6 atoms are coordinated by two oxygen atoms, which form an angular $[\text{AgO}_2]$ cluster.

The Rietveld refinement technique allows for identifying possible sites of Zn\textsuperscript{2+} cation occupancies in the $\alpha$-Ag$_{5-2x}$Zn$_x$WO$_4$ lattice. The substitution of Ag sites with Zn\textsuperscript{2+} cations represented through $[\text{AgO}_x]/[\text{ZnO}_y]$ (where $y$ can be 2, 4, 6, and 7) clusters was determined for $\alpha$-Ag$_{5-2x}$Zn$_x$WO$_4$ ($x = 0.10, 0.15, 0.20, 0.25$) solid solutions, and these are listed in Table 1 with their atomic occupation values.

The refinement results show that the Zn\textsuperscript{2+} cations occupy different sites in the $\alpha$-Ag$_3$WO$_4$ lattice. In the $\alpha$-Ag$_{5-2x}$Zn$_x$WO$_4$ ($x = 0.10$ and 0.15) samples, Zn cations occupy the Ag1 and Ag2 sites corresponding to $[\text{AgO}_2]$ and Ag6 sites of the $[\text{AgO}_2]$ clusters. For $\alpha$-Ag$_{5-2x}$Zn$_x$WO$_4$ ($x = 0.20$), the replacement takes place at these sites, as well as at the Ag4 site of the $[\text{AgO}_2]$ cluster. Finally, for $\alpha$-Ag$_{5-2x}$Zn$_x$WO$_4$ ($x = 0.25$), the substitutions occur in the Ag1, Ag2, Ag3, Ag4, and Ag6 sites of the $[\text{AgO}_2]$ (where $y = 7, 6, 4, 2$) clusters, respectively. With the increase in the amount of Zn\textsuperscript{2+}, there is a saturation of the substitution of Ag1, Ag2, and Ag6 sites, and the Zn\textsuperscript{2+} begins to occupy other sites—first the Ag4 and then the Ag3 sites. The $[\text{ZnO}_y]$ (where $y = 7, 6, 4, 2$) arrangements are represented, respectively, by distorted bipyramidal, tetrahedral, octahedral, and angular clusters. The random occupations of the Zn\textsuperscript{2+} cations lead to distortions in the $\alpha$-Ag$_3$WO$_4$ lattice observed by the different values of bond lengths and angles. These structural differences result in electronic order–disorder effects that, consequently, influence the $\alpha$-Ag$_3$WO$_4$ material as a whole, which is confirmed mainly by the morphology and optical properties.

The atomic Zn occupation values are illustrated in Table 1; however, to have greater accuracy of these values, another technique such as extended X-ray absorption fine structure (EXAFS) analysis is required.

**Structural Theoretical Analysis for $\alpha$-Ag$_{2-2x}$Zn$_x$WO$_4$.**

The Rietveld results show that orthorhombic $\alpha$-Ag$_3$WO$_4$ presents a very complex structure with different kinds of $[\text{AgO}_y]$ clusters (where $y$ can be 2, 4, 6, and 7) and that Zn\textsuperscript{2+} replacement can occur in any of these sites, depending on the Zn\textsuperscript{2+} concentration. To complement the experimental results and to study the effects of the presence of Zn\textsuperscript{2+} in the $\alpha$-Ag$_3$WO$_4$ structure, two theoretical models, namely, A and B, for $x = 0.25$ (stoichiometry coefficient) of Zn ions were selected, in which the Zn replacements and Ag vacancies were made considering the charge balance between the Ag$^+$ and Zn\textsuperscript{2+} cations. In model A, the Ag2 sites were replaced by Zn\textsuperscript{2+} cations, while in model B, the replacement was on the Ag4 sites, and the vacancies were allocated near the substitution sites in both models.

The theoretical results indicated that the Zn\textsuperscript{2+} could be located in both Ag2 and Ag4 positions. However, the Zn replacement on the Ag4 site (model B) was 0.15 eV more stable than that in the Ag2 site (model A). The $\alpha$-Ag$_{2-2x}$Zn$_x$WO$_4$ geometry showing the Zn additions and the Ag vacancy positions is depicted in Figure SI-4.

An analysis of the changes provoked by the substitution by Zn reveals that all clusters undergo modifications, exhibiting new coordination numbers and oxygen vacancies, as summarized in Table 2.

case of the \( \alpha{-}\text{Ag}_2\text{WO}_4 \) structure, but also are functions of deeper defects (oxygen vacancies, \( V_{O} \)) in the clusters presented in \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) caused by the rearrangement of the oxygen atoms around the cations. Therefore, in the \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) solid solutions, there are \([\text{WO}_4]^2^-\), \([\text{WO}_2\text{V}_0]^2^-\), \([\text{ZnO}_2\text{V}_0]^2^-\), \([\text{ZnO}_2\text{V}_0^2]^2^-\), and \([\text{AgO}_2\text{V}_0]^2^-\) distorted clusters that are responsible for the PL properties.

Micro-Raman Spectroscopy Analysis. Through the Raman it is possible to determine the structural order of the material. In accordance with the literature, the \( \alpha{-}\text{Ag}_2\text{WO}_4 \) structure is classified into the internal and external modes, due to the weak coupling among group \([\text{WO}_6]^-\) and the \( \text{Ag}^+ \) ion. Thus, the internal modes are related to the vibrational molecular units, where the centers of mass remains immobile and the external mode refer to the lattice phonon, which is attributed to the motion of \( \text{Ag}^+ \) ion.

Figure 3a illustrates the Raman spectra of \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) (\( x = 0, 0.05, 0.1, 0.15, 0.2, \) and 0.25) microcrystals prepared at 80 °C for 30 min by the CP method, and Figure 3b compares the experimental Raman vibrational modes of \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) microcrystals with the Raman-active modes calculated theoretically.

![Graph showing Raman spectra comparison](image-url)

Figure 3. (a) Raman spectra of the \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) (\( x = 0, 0.05, 0.1, 0.15, 0.2, \) and 0.25) microcrystals obtained by the CP method at 80 °C for 30 min and (b) comparison between the relative positions of theoretical and experimental Raman-active modes of \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) microcrystals.

According to the literature, there are 21 different vibrational modes in the tungstate with an orthorhombic structure. However, as can be seen in Figure 3a, 18 well-defined Raman-active modes were detected. These modes can be associated with the symmetric and asymmetric stretching among O–W–O moieties inside the \([\text{WO}_6]^-\) cluster, revealing peaks corresponding to the Raman-active internal modes \( A_1, B_2, B_3, \) and \( B_4 \) while the modes located at lower energy represent the torsion among W–O and Ag–O situated in the 50–1000 cm\(^{-1}\) range. All modes presented in Figure 3a are intense and well-defined, suggesting that all \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) (\( x = 0, 0.05, 0.1, 0.15, 0.2, \) and 0.25) microcrystals are structurally ordered at short-range. However, it is important to note that several modes were not observed probably due to their small intensities.

In this work, the active mode located in lower energy corresponds to translational \( A_{1g} \) (60 cm\(^{-1}\)) mode, and this refers to external or lattice phonons due to the \( \text{Ag}^+ \) heavy-migration movement in the rigid molecular unit. The strong interaction between the ions can cause an increase in the Raman-active mode intensity, and this occurs due to stretching and bending vibrations of shorter M–O bonds. Thus, the intense peak at 884 cm\(^{-1}\) is attributed to the \( A_{1g} \) mode caused by the symmetric stretching vibrations of [\( O=W=O \)] bonds of octahedral \([\text{WO}_6]^-\) clusters, as opposed to the lattice modifier assigned to \([\text{AgO}_2]^-\) (\( y = 2, 4, 6, \) and 7) clusters. Three Raman modes \( (A_{1g}, B_{2g}, \) and \( B_{1g} \) were also not observed, probably due to their small intensities.

Figure 3a displays that the Raman spectra for these samples presented a small change, indicating that the addition of \( \text{Zn}^{2+} \) ions in \( \alpha{-}\text{Ag}_2\text{WO}_4 \) does not cause drastic changes in the stretching, torsional, and bending vibrational modes of the orthorhombic structure. It occurs because of the \( \text{Zn}^{2+} \) substitutes the \( \text{Ag}^+ \) cation; however, some variations were expected. For example, the intense peaks at \( \sim 884 \) cm\(^{-1}\) show reductions in their intensities as the \( \text{Zn}^{2+} \) concentration is increased (see Figure 3a), due to structural distortions in the \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) microcrystal lattice produced by the \( \text{Zn}^{2+} \) substitution on the \( \text{Ag}^+ \) sites. These distortions also provoke changes in the bond lengths of the W–O distances in the \([\text{WO}_6]^-\) clusters. The result is in accordance with the Rietveld data, where a decrease in the cell volume as the concentration of \( \text{Zn}^{2+} \) was increased in the \( \alpha{-}\text{Ag}_2\text{WO}_4 \) lattice was observed.

One way to assess the quality of the theoretical models is to compare the vibrational modes. Figure 3b displays the Raman modes of the experimental samples, represented by (●), compared with our theoretical model (model B), illustrated as (★). Both experimental and theoretical results are in accordance with the literature (see Table SI-S). This fact indicates that our model provides an appropriate representation of the \( \alpha{-}\text{Ag}_{2-2}\zeta\text{ZnWO}_4 \) solid solutions. A slight variation of some modes can be detected, mainly at 443.9, 456.7, and 474.9 cm\(^{-1}\) (\( B_4 \)), which are associated with the stretching and bending vibrational modes of the \( \text{Zn}–\text{O} \) when compared with the experimental Raman modes (see Figure 3b and Table SI-S). This difference can be attributed to the different methods of synthesis, crystal size, and structural changes of bond distances \( \text{Ag}–\text{O}, \text{W}–\text{O}, \) and \( \text{Zn}–\text{O} \), and bond angles \( \text{Ag}–\text{W}–\text{O}, \text{Ag}–\text{W}–\text{Zn}, \) along the \([\text{AgO}_2]^-–\text{[WO}_6]^-–\text{[AgO}_2]^-–\text{[WO}_6]^-–\text{[ZnO}_2]^- \) (\( y = 2, 4, 6, \) and 7) frameworks.
FTIR Spectroscopy Analysis. FTIR data obtained in the interval of 200–1000 cm⁻¹ of the α-Ag₂₋₁Zn₂WO₄ (x = 0, 0.05, 0.10, 0.15, 0.20, and 0.25) microcrystals obtained by CP at 80 °C for 30 min.

Figure SI-5a–f presents the 14 IR-active vibrational modes assigned to the [WO₄²⁻] group, Ag–O and Zn–O bonds, and Zn–O–W bond angles.

The samples exhibit two intense absorption bands at 874 and 821 cm⁻¹ referring to bonds between the W–O–W and O–W–O antisymmetric stretching of the tetrahedral WO₄²⁻ group (see the inset in Figure SI-5). The 317 and 295 cm⁻¹ bands represent the IR-active vibrational internal modes associated with the symmetric bending vibrations and external modes attributed to the torsional within the WO₄²⁻ group, respectively.

Figure SI-5 shows that, for the samples with x > 0.05, there is a change in some modes of the W–O bonds and O–W–O bending, which can be observed in the range of 400–750 cm⁻¹. This behavior is due to distortions of the [AgO₃₋₁][WO₆]−[ZnO₂] (y = 2, 4, 6, and 7) clusters. Thus, the observed bands at 617 and 588 cm⁻¹ are assigned to the bridging oxygen atoms in the W₂O₄ asymmetric stretching, with the latter related to a small shift to lower wavenumbers (cm⁻¹) for samples with x = 0.20 and 0.25 of Zn²⁺ ion substitution (see Figure SI-5e,f). The vibrations of the O–W–O moiety also results in the active modes at 737 and 926 cm⁻¹, and in the W–O–W moiety the vibrations result in the mode at 671 cm⁻¹.⁵⁶

The absorption bands at 361 and 487 cm⁻¹ can be attributed to nonsymmetric deformation modes of Zn–O bonds, and the absorption bands at 911 and 1051 cm⁻¹ are related to the bending and stretching of the Zn–O–W framework.⁷⁰ FTIR spectra provided evidence that all α-Ag₂₋₁Zn₂WO₄ powders have an orthorhombic-type structure.

FE-SEM Morphological Analysis. Figure 4a–f presents the morphologies and microstructures of the α-Ag₂₋₁Zn₂WO₄ (x = 0, 0.05, 0.10, 0.15, 0.20, and 0.25) microcrystals obtained by CP at 80 °C for 30 min.

All samples are agglomerated with a polydisperse size distribution and shape (see Figure 4a–f), in accordance with our previous studies.³¹,¹⁷ On the basis of the Wulff construction, it is possible to find surface energy ratios to achieve the same morphologies obtained experimentally.⁵⁴,⁷¹,⁷² However, this is a simple method that can be applied to show how the Zn²⁺ replacement influences the crystal morphology and, consequently, the materials properties (see Figure SI-6).

An analysis of the images for the α-Ag₂WO₄ microcrystals displayed in Figure 4a–c shows several elongated rod-like structures, and it is possible to verify that α-Ag₂WO₄ microcrystals present a well-defined face with a hexagonal shape (see Figure 4b).³¹,¹⁷ It can be observed that some small α-Ag₂WO₄ nanocrystals, as well as large α-Ag₂WO₄ microcrystal surfaces, were not diffused within the interior. According to Cavalcante et al.,¹⁷ this behavior is because the partial diffusion of these small microcrystals thought larger particles of α-Ag₂WO₄ and/or that thermal energy that was not enough to the normal growth rate of the α-Ag₂WO₄ microcrystals. According to Roca et al.,¹⁷ α-Ag₂WO₄ microcrystals with a hexagonal rod-like shape have a preferential growth along the [010] direction. Coming from the vacuum structure previously obtained, the Wulff construction of the hexagonal rod-like shape can be obtained by destabilizing the (010) surface (increasing its energy) and stabilizing the (101) surface (decreasing the energy). The relative surface energies of this morphology are described in Figure SI-6b.

In the solid solution with x = 0.05 of Zn²⁺ occurs a modification in the microcrystal shapes and sizes, as can be seen in Figure 4d–f. These figures illustrate the formation of rod-like microcrystals with crystallographic face-squared shapes (see Figure 4e,f). The average size of these particles is also smaller.
than the pure $\alpha$-Ag$_2$WO$_4$. Thus, the Wulf construction of this morphology was reached destabilizing the (001) surface and stabilizing the (100) surface (see Figure SI-6c). It is worth mentioning that the elongation of these particles is provided by the decrease in the (001) surface energy in relation to the (100) and (010) surfaces. Therefore, this information allows one to know how the Zn$^{2+}$ influences the particle growth, by providing a stabilization of the (101) surface with respect to the (100), (010), and (001) surfaces. The surface energy values in thermodynamic equilibrium can be found in Figure SI-6c.

Figure 4g–i presents the $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ ($x = 0.10$) solid solution, where a similar behavior of $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ ($x = 0.05$) microcrystals is observed, and this can be proved through the Wulf construction (see Figure SI-6c); however, the microcrystals show a more rugose surface and a decrease in the average size (see Figure 4h).

Figure 4j–l shows the $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ ($x = 0.15$) microcrystals, which exhibit a rugose surface and face-quasi-squared shape, while also showing a curved surface (see Figure 4k,l). Finally, in the $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ ($x = 0.20$ and 0.25) microcrystals the Zn$^{2+}$ caused a pronounced change in the morphology was reached destabilizing the (001) surface and to the silver vacancies, there is a spontaneous formation of oxygen vacancies in the clusters that creates irregularities or surface defects in $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ (0.05 $\leq x \leq 0.25$) microcrystals, indicating a polydisperse growth nature (see the morphology in the Figure S inset).

UV–Vis Absorption Spectroscopy Analysis and Band Structures of $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ Microcrystals. The optical band gap values ($E_{\text{gap}}$) of $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ ($x = 0, 0.05, 0.10, 0.15, 0.20, 0.25$) microcrystals were calculated by the Wood-Tauc method and Kubelka–Munk function. The gap energy values were obtained through the equations discussed in previous works. Additionally, on the basis of our theoretical calculations, the electronic transitions for the $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ ($0 \leq x \leq 0.25$) systems are governed by an indirect transition. This information was used for the band gap energy estimation in the Wood-Tauc method.

Table 3 presents the estimated band gap values for $\alpha$-Ag$_{2-x}$Zn$_x$WO$_4$ ($x = 0, 0.05, 0.10, 0.15, 0.20, 0.25$) microcrystals obtained by CP at 80 °C for 30 min. The UV–vis spectra of these samples are present in Figure SI-7.

As observed in Table 3, the experimental $E_{\text{gap}}$ values show a slight decrease as the presence of Zn$^{2+}$ ions in the $\alpha$-Ag$_2$WO$_4$ lattice increases.

The study of these electronic transitions can be evaluated through theoretical calculations. Therefore, Figure 6a–c illustrates the band structures of pure $\alpha$-Ag$_3$WO$_4$ for model A and model B. Typically, the introduction of impurities in the lattice tends to decrease band gap due to the creation of new intermediate levels in the forbidden region, as also observed in our model as well. This tendency can occur not only because of the insertion of impurities but also by the disordered structure as structural defects at medium range, local band distortions, intrinsic surface states, and interfaces.

By means of the band structure analysis, it was noticed that the pure $\alpha$-Ag$_2$WO$_4$ and the two models with the Zn replacement are typically characterized by indirect electronic transitions. In the band structure of pure $\alpha$-Ag$_2$WO$_4$, the top of
the valence band (VB) is located at the T point, and the bottom of the conduction band (CB) is at the Γ point; in models A and B, the bottom of the CB is located at the T point, and the top of the VB is placed at the U and R points, respectively. Even though the band gaps of the two models are similar, the indirect characteristic of the band gap was retained, although the change of $U - T$ to $R - T$ transition. This result confirms that the location of the replacement (in the Ag2 site in model A; in the Ag4 site in model B) affects the transition energy. The comparison between the energies revealed that model B is more stable than model A. Additionally, this stability resulted in the reduction in the band gap value due to the modification of energy levels, which can be better evaluated by the DOS analysis.

**Density of States.** The DOS of pure $\alpha$-Ag$_2$WO$_4$ and the two models were also studied to give information in relation to the electronic transitions. Figure 7 shows the total DOS for pure $\alpha$-Ag$_2$WO$_4$ and the models with Zn replacement (models A and B). For all models, the projected DOS on the W atom is principally determined in the CB with 5d orbitals. The VB is mainly resulting from the hybridization of 2p and 4d orbitals from O and Ag atoms, respectively. The Zn atoms present a

![Figure 6. Band structure of (a) pure $\alpha$-Ag$_2$WO$_4$ (b) model A, and (c) model B.](image)

![Figure 7. DOS projected in (a) pure $\alpha$-Ag$_2$WO$_4$ (b) model A, and (c) model B.](image)
small contribution for both bands. When we analyze these results, it is possible to notice that the region of the band gap underwent an enlargement in both bands. This fact is linked with the kinds of defects that the Zn$^{2+}$ replacement created in the α-Ag$_2$WO$_4$ bulk.

There might be different defects in the structure; for example, shallow and deep defects. The first one is related to structural order–disorder effects, such as bond stretching or bond bending, whereas the deep defect is assigned to oxygen vacancies ($V'$). When we induce the Zn$^{2+}$ substitution in the theoretical models, changes in the α-Ag$_2$WO$_4$ bulk (pure model) were observed, mainly causing different types of clusters. These structural deformations and oxygen vacancies are present in [AgO$_x$], [ZnO$_y$] ($y = 2, 4, 6, 7$), and [WO$_x$] clusters.

**Photoluminescence.** PL spectra of the α-Ag$_{x-2}$Zn$_2$WO$_4$ ($x = 0, 0.05, 0.10, 0.15, 0.20, 0.25$) samples prepared by the CP method at 80 °C for 30 min with a 350.7 nm excitation are shown in Figure 8. The PL studies are an important way to evaluate the electronic levels and to analyze the theoretical models.

![Figure 8](image)

**Figure 8.** Emission spectra of the α-Ag$_{x-2}$Zn$_2$WO$_4$ ($x = (a) 0, (b) 0.05, (c) 0.10, (d) 0.15, (e) 0.20, and (f) 0.25$) microcrystals obtained by the CP method at 80 °C for 30 min; excited at 350.7 nm with a krypton ion laser.

Figure 8 shows the PL emissions from 350 to 850 nm for all of the samples. It is possible to observe a wide band with maximum intensity emission in the violet–blue range between 450 and 465 nm and another in the orange–red region between 606 and 690 nm, related to cluster-to-cluster charge transfer processes. All spectra present a wide band in the visible range, indicating that the emission is a multilevel process, involving the contribution of various energy states in the band gap. When the Zn$^{2+}$ ions are doped into α-Ag$_2$WO$_4$, the red emission is favored, and it is linked to the deep defects, which are, in turn, linked to the oxygen vacancies presented in the clusters. In α-Ag$_2$WO$_4$ microcrystals, it is supposed that the Zn$^{2+}$ ion replaces the Ag$^{+}$ ion. Thus, the replacement of bivalent ion for a monovalent requires a charge balance of the lattice.

![Figure 9](image)

**Figure 9.** The deconvolution of the PL spectra, four curves at $x = 441$ (blue), 491 (green), 630 (red), and 768 nm (orange) were possible to cover all of the visible electromagnetic spectrum. These results show a different behavior in each sample as the concentration of Zn$^{2+}$ in the α-Ag$_{x-2}$Zn$_2$WO$_4$ solid solutions was increased. However, these results reveal an elevated percentage of the red and orange area, indicating a higher amount of deep defects compared to shallow defects. This behavior is different from the pure α-Ag$_2$WO$_4$ sample, which favors the blue and green area, corresponding to shallow structural defects. These oscillations in the PL emissions corroborate with the Rietveld data, which show a random distribution of Zn$^{2+}$ ions on the Ag$^+$ sites. The replacement of Ag$^+$ by Zn$^{2+}$ in α-Ag$_{x-2}$Zn$_2$WO$_4$ forms a complex structure with ionic bonds and, consequently, forms complexes with strong bonds. Thus, the substitutions occur in different clusters as the number of Zn$^{2+}$ ions are increased, causing a red shift, which is linked to the increase in the amount of deep defects. These results were confirmed by theoretical models, where it was possible to notice different clusters of [ZnO$_y$V$_x$], [ZnO$_4$2V$_x$], [WO$_x$V$_y$], [WO$_4$2V$_x$], and [AgO$_y$] ($y = 4, 5, 6$), as demonstrated in Section 3.4 (Structural Theoretical Analysis).

The oxygen vacancies can be found in different charge states in the disordered lattice, such as [WO$_x$V$_y$], [WO$_x$2V$_y$], [ZnO$_y$V$_x$], and [ZnO$_4$2V$_x$], where these donate electrons and are neutral relative to the lattice. [WO$_x$V$_y$], [WO$_x$2V$_y$], [ZnO$_y$V$_x$], and [ZnO$_4$2V$_x$] are singly ionized states and donate and capture electrons, while [WO$_x$V$_y$], [WO$_x$2V$_y$], [ZnO$_y$V$_x$], and [ZnO$_4$2V$_x$] are doubly positively charged states in the lattice and capture electrons. Thus, these oxygen vacancies generate new energy states into the band gap, being attributed to [WO$_x$], [AgO$_y$], or [ZnO$_y$] complex clusters.
However, other factors may also be involved in the PL of the \( \alpha{-}\mathrm{Ag}_2\mathrm{WO}_4 \) samples, such as particle aggregation, differences in the size and the morphology, as well as surface characteristics. Therefore, changes in the shapes and sizes of the particles are considered crucial for the variations of the luminescence emission profile. Thus, it is possible to compare the changes in the PL emission obtained in this work with the morphology of the microcrystals by increasing the amount of Zn\(^{2+}\) in the lattice (see Figures 4a–r), where significant changes in the sizes and shapes of the particles and their surfaces were observed.

4. CONCLUSIONS

In summary, \( \alpha{-}\mathrm{Ag}_2\mathrm{Zn}_x\mathrm{WO}_4 \) \((0 \leq x \leq 0.25)\) solid solutions crystals were synthesized successfully by the CP method and, for first time, the introduction of Zn\(^{2+}\) ions to control the crystal characteristics and optical properties was investigated. XRD patterns and Rietveld refinement data showed that the \( \alpha{-}\mathrm{Ag}_2\mathrm{Zn}_x\mathrm{WO}_4 \) \((0 \leq x \leq 0.25)\) microcrystals were monophasic with orthorhombic structure and space group \( \mathrm{Pn2n} \) and showed that Zn replacement occurred randomly in Ag sites in the \( \alpha{-}\mathrm{Ag}_2\mathrm{WO}_4 \) structure, depending on the Zn concentration. Thus, structural theoretical analysis based on first-principles calculations showed that Zn replacement in \( \alpha{-}\mathrm{Ag}_2\mathrm{WO}_4 \) structure is more favorable on the Ag4 site (tetracoordinated).

MR and FTIR spectroscopies were employed to evaluate the vibrational modes, and the results have confirmed that all vibrational modes are characteristic of the orthorhombic structure. The addition of Zn\(^{2+}\) ions in \( \alpha{-}\mathrm{Ag}_2\mathrm{WO}_4 \) was unable to modify the stretching, torsional, and bending active vibrational modes. The theoretical values of the Raman spectra are in agreement with previously reported values and the experimental results.
FE-SEM images revealed that the incorporation of Zn²⁺ in the α-Ag₂WO₄ structure affected the shape and size of the microcrystals. On the basis of the Wulff’s theorem and theoretical results, a model was elaborated to determine the surface energies of the α-Ag₂WO₄ crystals with atomic-level resolution and the crystal morphologies at equilibrium. Particle shape transformations of the α-Ag₂WO₄ were estimated by controlling the ratio between surface energy values of each face. The Ag substitution by Zn decreased the number of exposed surfaces, and the shape changed from roll-like to curved surfaces in α-Ag₂WO₄ and α-Ag₂₋ₓZnₓWO₄ (x = 0.25), respectively.

The UV–vis spectrum indicated that, for α-Ag₂WO₄ microcrystals and α-Ag₂₋ₓZnₓWO₄, the band gap value was governed by an indirect transition. The PL behavior of the surfaces in α-Ag₂WO₄ was estimated by controlling the ratio between surface energy values of each face. The Ag substitution by Zn decreased the number of exposed surfaces, and the shape changed from roll-like to curved surfaces in α-Ag₂WO₄ and α-Ag₂₋ₓZnₓWO₄ (x = 0.25), respectively.
