ABSTRACT

Objectives. This study has investigated the influence of Titanium dioxide nanotubes ($\text{TiO}_2\text{-nt}$) addition to self-adhesive resin cement on the degree of conversion, water sorption, and water solubility, mechanical and biological properties.

Methods. A commercially available auto-adhesive resin cement (RelyX U200TM, 3M ESPE) was reinforced with varying amounts of nanotubes (0.3, 0.6, 0.9 wt%) and evaluated at different curing modes (self- and dual cure). The DC in different times (3, 6, 9, 12 and 15 min), water sorption (W_s) and solubility (S_l), 3-point flexural strength (σ_f), elastic modulus (E), Knoop microhardness (H) and viability of NIH/3T3 fibroblasts were performed to characterize the resin cement.

Results. Reinforced self-adhesive resin cement, regardless of concentration, increased the DC for the self- and dual-curing modes at all times studied. The concentration of the $\text{TiO}_2\text{-nt}$ and the curing mode did not influence the W_s and S_l . Regarding σ_f , concentrations of both 0.3 and 0.9 wt% for self-curing mode resulted in data similar to that of dual-curing unreinforced cement. The E increased with the addition of 0.9 wt% for self-cure mode and H increased with 0.6 and 0.9 wt% for both curing modes. Cytotoxicity assays revealed that reinforced cements were biocompatible.

Significance. $\text{TiO}_2\text{-nt}$ reinforced self-adhesive resin cement are promising materials for use in indirect dental restorations. Taken together, self-adhesive resin cement reinforced with $\text{TiO}_2\text{-nt}$ exhibited physicochemical and mechanical properties superior to those of unreinforced cements, without compromising their cellular viability.

1. Introduction

Self-adhesive resin cements were developed to clinical time by simplifying cementation procedures due to the elimination of the acid etching and application of adhesive steps [1–3]. Its adhesive properties are attributed to the presence of the modified acidic group's methacrylate monomers that allows the infiltration and demineralization of the substrate, that result in micromechanical retention and chemical bonding with hydroxyapatite [3].

However, the presence of these acidic monomers in self-adhesive resin cements may adversely affect the degree of conversion (DC) because of its interference with the amine coinitiator, which results in changes in the curing [4] and the loss of some physical and mechanical properties [5–7]. Moreover, being dual-cured, not all cements present the same conversion rates of monomers when self- or/and light-activated. In general, light-activation promotes higher conversion of monomers [8].

To improve certain properties of resin materials, the addition of titanium dioxide nanostructures have demonstrated positive results in the behavior of polymeric materials such as resin composites [9,10], flowable resin composites [11], orthodontic resin cements [12] and glass ionomer cements [13]. The decrease in size of different oxides at the nanoscale promotes a wide range of applications in different materials because their behavior changes when compared to the bulk size [14], making it an effective functional material [15]. Nano-sized oxides such as TiO₂ can provide unique physical and chemical properties due to their small size and high density of surface sites, increasing their reactivity and interaction with the environment [16]. In particular, the nanotubes' shape provides a large surface area that can give rise to strong internal and external interactions with the matrix in which they are embedded, chemical stability and a high refractive index [17].

Whereas oxides at the nanoscale can be easily incorporated into the resin-based materials when manipulated, adding these to the self-adhesive resin cement can be an alternative to improve the overall performance of the indirect restoration. Therefore, the aim of the current investigation was to determine the physical-chemical, mechanical and biological properties of a self-adhesive resin cement (RelyX U200TM—Seefeld, Germany) in the presence of TiO₂-nt at three different concentrations: 0.3%, 0.6% and 0.9% (w/w).

2. Materials and methods

2.1. Experimental design

The factor under study was the incorporation of different concentrations of TiO₂-nt (w/w) into self-adhesive resin cement RelyX U200TM. For degree of conversion (DC), the study factors were as follows: (1) concentration of TiO₂-nt (0.3, 0.6 and 0.9 wt.%), (2) curing mode dual- and self-curing and (3) time (3, 6, 9, 12 and 15 min). For water sorption (WS) and solubility (SL), flexural strength (*σ_f*), modulus of elasticity (E) and hardness (H), the study factors were: (1) concentration of TiO₂-nt (0.3, 0.6 and 0.9 wt%) and (2) curing mode (dual- and self-curing).

For cell viability study, the factors were as follows: (1) concentration of TiO₂-nt (0.3, 0.6 and 0.9 wt.%) and (2) time (24, 48 and 72 h). Two polymerization conditions were used: self- and dual-cured polymerization. For the self-curing condition, the cement handling and the specimens' preparation were performed in an environment with room light. Thirty minutes after cement handling, specimens were removed from the custom devices used in each test and stored in distilled water at 37 °C. For the dual-curing condition, the specimens were handled in an environment with room light, embedded in custom devices used in each test of the study. Nine minutes after handling of self-adhesive resin cement, the light source 780 mW/cm³ DB LED 686 (Dabi Atlante, Ribeirão Preto, Brazil) was applied for 20 s in different areas of the specimens so that the whole specimen was reached by light. The 9 min time was used once delay in light activation had shown to improve properties of resin-based cements [18,19].

The specimens of the self-adhesive resin cement were randomly assigned into 8 groups: S0T = self-adhesive resin cement in self-cure condition, which has no TiO₂-nt; S03 = self-adhesive resin cement in self-cure condition with the addition of 0.3 wt.% of TiO₂-nt; S06 = self-adhesive resin cement in self-cure condition with the addition of 0.6 wt.% of TiO₂-nt; S09 = self-adhesive resin cement in self-cure condition with the addition of 0.9 wt.% of TiO₂-nt; DCT = self-adhesive resin cement in dual-cure condition, which has no TiO₂-nt; D03 = self-adhesive resin cement in dual-cure condition with the addition of 0.3 wt.% of TiO₂-nt, dual cure; D06 = self-adhesive resin cement in dual-cure condition with the addition of 0.6 wt.% of TiO₂-nt; D09 = self-adhesive resin cement in dual-cure condition with the addition of 0.9 wt.% of TiO₂-nt.

2.2. Specimen preparation

TiO₂-nt were obtained from a commercial mixture of anatase TiO₂ powder (Sigma-Aldrich, St. Louis, USA) mixed with an alkaline solution of sodium hydroxide (NaOH; 10 M), which remained for 24 h at 120 °C in an atmospheric pressure environment Teflon container. Then, the mixture was washed with deionized water and hydrochloric acid (HCl; 0.1 M) sequentially and repeatedly until reaching a pH of 4. After that, the mixture were placed in a furnace at 200 °C for 24 h to eliminate the liquid phase and to obtain the final powdered material [20]. The nanotubes were measured with open source Image J software and had an average diameter of 10 nm and were 200 nm in length, formed by a single sheet of spiral-wound TiO₂. The image was obtained by Transmission Electron Microscopy (TEM) (CM 200, Phillips, Netherlands) with electrons acceleration of 200 kV [20]. The resin cement that had the same portion of base and catalyst paste dispensed by packing clicker was dispensed on a mixing pad and weighed on a precision scale of 0.0001 g (Denver Instrument, São Paulo, Brazil). Then, the nanotubes were weighed with the value corresponding to the resin cement weigh. TiO₂-nt was manually added to the base paste and handled for 10 s. Then, the base paste and TiO₂-nt were mixed with the catalyst paste for another 10 s.

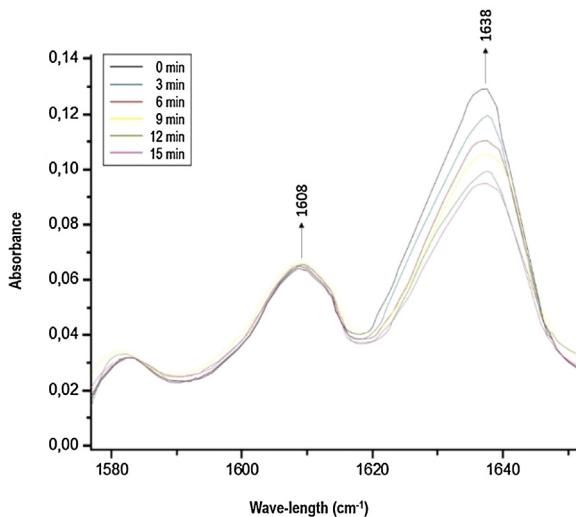

Fig. 1 – Peaks at 1608 and 1638 cm⁻¹ identified in the spectral bands used for calculating the degree of conversion before polymerization (0 min) and after mixing base and catalyst pastes (3, 6, 9, 12 and 15 min).

2.3. Degree of conversion

The DC was evaluated by Fourier transformed infrared spectroscopy (IRPrestige-21, Shimadzu, Tokyo, Japan). The analysis was performed in reflectance mode using the attenuated total reflectance (ATR) accessory (MIRacle, Pike Technologies, Madison, USA). Cement specimens ($n=3$) were analyzed at 0, 3, 6, 9, 12 and 15 min after mixing base and catalyst pastes under self- and dual-cure polymerization conditions. After mixing the pastes and adding or not the nanotubes, small portions were placed covering the ATR crystal and the initial FT-IR spectra was obtained. For the self-cured groups, the resin cements were kept undisturbed and protected from light. For dual-cured groups, the light source 780 mW/cm³ was applied for 20 s on self-adhesive resin cement 9 min after the application on ATR crystal. The infrared spectrum of the specimen was obtained in the range of 1560–1760 cm⁻¹ with 10 scans and consecutive resolution of 4 cm⁻¹. Spectral bands were obtained, and the peak wavelength of aliphatic 1638 cm⁻¹ (functional groups C=C) and aromatic 1608 cm⁻¹ was identified for each time studied (Fig. 1). The DC was calculated using the equation:

$$DC(\%) = 100 \times [1 - (R_{T\min}/R_{0\min})] \quad (1)$$

where R is the ratio of the absorbance at 1638 cm⁻¹ and absorbance 1608 cm⁻¹ within the time determined for each record of the analysis (represented by T in the equation).

2.4. Sorption (WS) and solubility (SL)

For WS and SL, specimens were prepared ($n=8$) for each of the 8 groups using a metallic mold with a cylindrical shape of 10 mm in diameter and 1-mm-thick. The method used was based on the ISO 4049 [21]. The specimens were kept in dry and dark storage for 24 h, and then transferred to a desicca-

tor at $37 \pm 1^\circ\text{C}$. After 22 h in the first desiccator, the specimens were removed, stored in a second desiccator at $25 \pm 1^\circ\text{C}$ for 2 h, and then weighed, using a 0.0001 precision analytical balance (Denver Instrument, São Paulo, Brazil) until a constant weight for each specimen (m_1) was obtained (with no more than a ± 0.0001 g variation). The specimens were then immersed in deionized water at 37°C . At fixed intervals, the specimens were removed from the water, blot-dried (in sequence using two absorbent papers) and weighed until a constant mass (m_2) was obtained. The specimens were then stored in a desiccator in the presence of silica at 37°C and weighed until a constant weight (m_3) was obtained, following the cycle described above for m_1 . The values for WS and SL (in $\mu\text{g}/\text{mm}^3$) were calculated using the following equations:

$$WS = (m_2 - m_3)/V \quad (2)$$

$$SL = (m_1 - m_3)/V \quad (3)$$

where m_1 is the specimen weight before immersion, m_2 is the specimen weight after immersion, m_3 is the specimen weight after immersion and desiccation, and V is the volume of the specimen.

2.5. Mechanical properties

2.5.1. Flexural strength (σ_f) and elastic modulus (E)

Resin cement bars ($n=10$) were made for each group according to the polymerization conditions and addition of TiO₂-nt. After mixing, the resin cement was inserted in a stainless steel mold for standardizing specimens dimensions (2 × 2 × 25 mm), as per ISO 9917-2 [22]. The specimens remained in distilled water at 37°C for 24 h before testing. The σ_f at three points was determined using a universal testing machine (Instron, Barueri, Brazil) with load-cell connected 50 N and a crosshead speed of 0.5 mm/min. The dimensions of the specimens were previously measured with a digital caliper (Starrett, Itu, São Paulo, Brazil). To perform the 3-point σ_f , the specimens were placed on the device with a distance of 12 mm between the lower cylindrical support and the load applied to the center of the upper metal rod. Flexural-strength values were determined according to the equation:

$$\sigma_f = 3PL/(2wb^2) \quad (4)$$

where P is fracture load, (N) L is the distance between the supports (12 mm), w is the specimen width (mm) and b is the thickness (mm).

2.5.2. Surface microhardness

Microhardness measurements were obtained from 48 disc-shaped specimens (10 × 2 mm; $n=6$) on the surface using a microhardness instrument (Buehler, Lake Bluff, USA) with a Knoop diamond under a 50 g load for 10 s. Before the measurements, the surface of specimens was polished with 600, 800 and 1200-grit SiC (Extec CORP., Enfield, CT, USA, #1060-524) papers for 2 min each, respectively. The measurement of the indentation was performed immediately after the period of 10 s. Five indentations spaced 0.5 mm from each other were

made in the central area of each specimen, and the arithmetical average was used for subsequent statistical analysis.

2.6. Biological analyses

2.6.1. Preparation of specimens

Four disks ($10\text{ mm } \phi \times 2\text{ mm}$) of resin cement were prepared for each concentration-studied TiO_2 -nt. After light curing, the specimens were autoclaved separately. To evaluate cell viability ($n=8$), an MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay was performed using only the dual-curing condition. The studied groups were DCT, D03, D06, D09, positive control (CP) and negative control (CN).

2.6.2. Cell culture

For cell culture, mouse fibroblasts were used in the NIH3T3 line P13 (ATCC®, Manassas, USA). The cells were cultured in DMEM-Dulbecco's modified Eagle (Aldrich® Sigma, St. Louis, USA), supplemented with 1% antibiotics (penicillin/streptomycin from Gibco®, Waltham, USA) and 10% FBS (fetal bovine serum from Gibco®) and remained incubated at 37°C with 5% carbon dioxide (CO_2). After reaching a subconfluence stage, a subculture was formed using the trypsin enzyme responsible for dissociating the culture bottle cells (0.25% trypsin, 1 mM EDTA from Sigma-Aldrich®). After 5 min in an oven at 37°C with 5% (CO_2), the trypsin was inactivated with DMEM culture medium with 10% FCS. The cells were transferred to a 50-ml falcon tube (Corning, NY, USA) and centrifuged at 1200 rpm for 5 min at 20°C . After centrifugation, the supernatant was discarded, and the cells were suspended again in a fresh DMEM medium with 10% FCS. After that, the cell count was performed using a trypan blue protocol optical microscope (Olympus, Japan). This dye is responsible for staining the viable cells as it penetrates the dead cells because their membranes can no longer eliminate it. Subsequently, the cells were plated in 96-well microplates (TPP®, Trasadingen, Switzerland) for a colorimetric assay, 8-well microplates for each group. The resin-cement specimens were placed in contact with the culture medium following the recommendations of ISO 10993-5 [23] ($1\text{ cm}^2/\text{ml}$). To this end, the total area of the disks was calculated (28.26 cm^2) to evaluate the amount of conditioned media (28.26 ml). The specimens remained in the oven at 37°C for 24 h. After this, the pH at which the disks were immersed was measured. For the viability assays, cells were plated $2 \times 10^3/\text{well}$ in 96-well plates (TPP®). After the

enrollment period of 24 h, the culture medium was replaced by DMEM 10% FCS conditioned with the cement specimens. Each plate was examined at an experimental time of 24, 48 and 72 h after the addition of conditioned medium. After each experimental period, the culture medium was removed, the cells were washed with phosphate buffered saline solution (PBS) and then an MTT reduction test.

2.6.3. Analysis of cell metabolism MTT assay

During each experimental period (24, 48 and 72 h), the cells were washed with PBS and then incubated in 0.5 mg/ml solution (MTT/DMEM) for an MTT assay. This solution was prepared at the time of use and filtered through a Millipore filter (0.22 mM) before being added to the plates. After this procedure, the plates remained in the greenhouse for 4 h at 37°C and 5% CO_2 ; then, the solution was removed, and the insoluble pigment reduced intracellularly was taken up in dimethylsulfoxide and left at room temperature for 30 min. The absorbance was measured at 562 nm wavelength reader (Synergy H1 monochromator-based, Biotek, Winooski, USA).

2.7. Statistical analyses

Data were analyzed using the Shapiro-Wilk normality test. The DC data were subjected to ANOVA with repeated-measures followed by Tukey's HSD ($\alpha=0.05$). WS, SL and each mechanical and biological property were submitted to two-way ANOVA and Tukey's HSD ($\alpha=0.05$).

3. Results

3.1. Degree of conversion

The mean values and standard deviations are detailed in Table 1.

There were significant differences between curing mode ($p=0.000$) and addition of nanotubes ($p=0.0000$). The interaction was also found to be significant ($p=0.0000$). The DC increases with time ($p=0.0000$). The addition of TiO_2 -nt, regardless of concentration, increased the DC values for both self- and dual-curing conditions at all times studied. The DC analysis at 3 min showed that the addition of 0.3% (S03=26.76%; D03=26.11%) and 0.9% (S09=25.62%; D09=26.05%) of TiO_2 -nt in the self-adhesive resin cement in both polymerization conditions showed the highest val-

Table 1 – Mean values and standard deviations of the DC (%). Within a column or row, values denoted by similar superscript letters are not significantly different ($p > 0.05$).

ues, similar to the SCT group at 12 min ($\text{SCT}=25.89\%$). At 6 min, an addition of 0.9% TiO_2 -nt ($\text{S09}=40.46\%$; $\text{D09}=39.89\%$) showed higher results when compared to other groups. The DCT control group showed an increase in the DC at a mean time of 9 min (28.51%) compared to the SCT group (14.62%) that received no light. Regardless of the TiO_2 -nt concentration added, S03, S06 and S09 showed higher values than the DCT group at 9 and 12 min. At 15 min, only S06 group was similar to the DCT group. At 15 min, the best result was found in the D03 group (48.09%), with statistical differences for S09 (46.51%). S03 (45.76%), D06 (45.77%) and D09 (45.51%) had no difference between each other. The SCT group showed the lowest DC.

3.2. WS and SL

There was no significant difference between groups regardless the concentration of nanotubes added and polymerization condition ($p > 0.05$). The mean values and standard deviations for WS and SL can be observed in Table 2. After a Pearson correlation analysis, an 80% correlation ($r > 0.800$) was observed between WS and SL in all groups studied regardless of the polymerization condition. Figs. 2 and 3 show the direct relationship between the WS and SL of each group for the self- and dual-curing conditions, respectively.

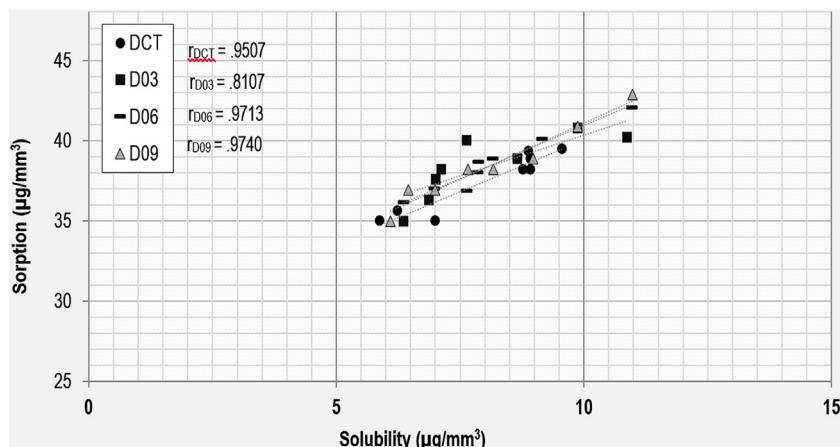

Fig. 3 – Correlation between WS and SL for the dual-curing mode.

Table 3 – Mean values and standard deviation (SD) of flexural strength (σ_f), elastic modulus (E) and Microhardness (H) for each group. Within a row, values denoted by similar superscript letters are not significantly different ($p > 0.05$).

Groups								
	SCT	S03	S06	S09	DCT	D03	D06	D09
σ_f (MPa)	35.40 ^c	59.40 ^{a,b}	41.68 ^{c,d}	55.22 ^{a,b,c}	70.72 ^b	57.61 ^{a,b}	44.71 ^{a,c,d}	58.43 ^{a,b}

SD	±1.05	±2.63	±1.97	±1.61	±0.64	±1.53	±1.71	±1.16

3.3. Flexural strength (σ_f), elastic modulus (E) and microhardness (H)

The mean values and standard deviations are detailed in **Table 3**. For σ_f , there were significant differences between curing mode ($p = 0.001$) and addition of nanotubes ($p = 0.0002$). The interaction was also found to be significant ($p = 0.0000$). For E, there were significant differences between curing mode ($p = 0.006$) and addition of nanotubes ($p = 0.0000$). The interaction was also found to be significant ($p = 0.0009$). For Microhardness, significant differences were observed only for curing mode ($p = 0.001$).

Adding 0.3% TiO_2 -nt (S03) and 0.9% (S09) increased the σ_f of the cement in the self-curing mode with similar values to the control group in the dual condition (DCT). As for the dual-curing mode, the addition of nanotubes did not increase the value of the σ_f and the addition of 0.6% (D06) decreased the value compared to the control (DCT). The average E increased with the addition of 0.9% for self-curing condition.

The addition of 0.6% (S06 and D06) and 0.9% (S09 and D09) of TiO_2 -nt cement increased microhardness values when compared to the control groups (SCT and DCT). The addition of 0.3% (S03 and D03) nanotubes resulted in hardness data similar to SCT and DCT and the groups with 0.6 and 0.9% TiO_2 -nt.

3.4. Cell viability

The addition of TiO_2 -nt at different concentrations did not affect the cement pH values (**Table 4**).

Table 4 – Control and experimental groups and their respective pH values.

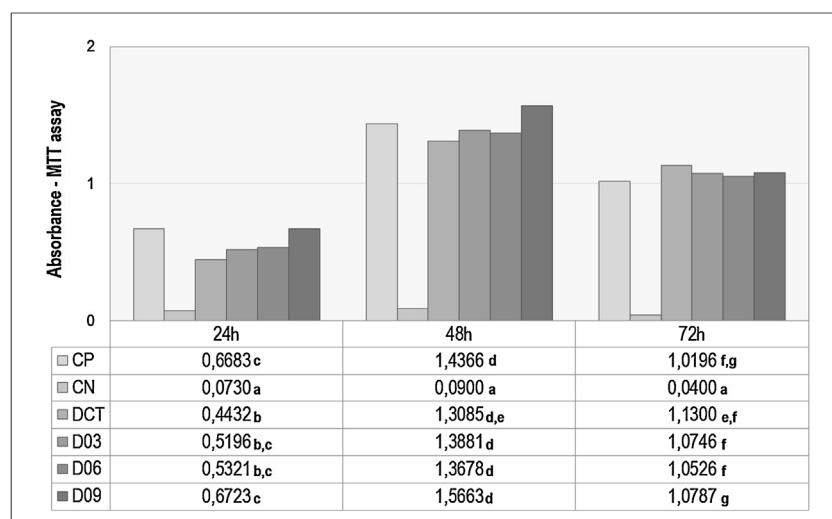

Groups						
	CP	CN	DCT	D03	D06	D09
pH ($p = 0.6967$)	7.20	7.97	7.60	7.56	7.82	7.69

The result of the MTT colorimetric assay is shown in **Fig. 4**. Within 24 h, D03, D06 and D09 had achieved a similar result to that of the CP group. The DCT group had lower absorbance values than CP, which was used as a benchmark, with a statistically significant difference ($p = 0.000$). At 48 h, no groups showed a significant difference compared to the CP group, with the exception of CN. At 72 h, there was a decrease in cell viability. However, the profile was similar to the 48-h-period in that all groups had results similar to those of CP.

Observing the images obtained by optical microscopy at the end of each period (**Fig. 5**), it was found that within 72 h, the wells were at confluence. Due to the lack of space, cell death occurred, confirming the decrease in viability during this period.

4. Discussion

The addition of TiO_2 nanostructures to dental polymers has shown promising results [9–11,13]. Overall, positive results were found in the current investigation for a self-adhesive resin cement with TiO_2 -nt reinforcement, and the

**Fig. 4 – MTT reduction colorimetric assay at 24, 48 and 72 h.**

physical-chemical, mechanical and biological behaviors were improved. These improvements, especially in the self-curing condition, are important for the longevity and clinical performance of this cement.

The dual-curing condition proposed in this study simulates the use of the self-adhesive resin cement in the cementation of indirect restorations containing infrastructures that do not allow the passage of light, such as Y-TZP, in which the cement on the restoration margins receives the curing light after a few minutes of cementation.

The dual-curing protocol performed in this study is based on the one employed by Soares et al. [19] in which the light-activation was performed 6 min after the handling of the resin cement without impairing its mechanical properties. This delay in light activation has shown to improve properties of resin-based cements [18].

Regardless of the percentage added (0.3%, 0.6%, or 0.9%), the DC was higher at all time points (3, 6, 9, 12, and 15 min) compared to the control for both polymerization modes. The non-reinforced cement did not reach the same DC in SCT when compared to the condition in which it was submitted to light-activation (DCT), which is in agreement with other studies [6,24,25]. Thus, the chemical reaction alone of the evaluated dual-cured resin cement without light-activation seems therefore not to be sufficient to achieve reasonable levels of conversion of C=C double bonds for polymer formation after 15 min of mixing. The photo-initiator system allows a fast reaction and high conversion when the materials are subjected to light-activation [6].

The addition of 0.3% to 0.9% of TiO₂-nt in the self-curing mode increased the DC to values close to the ones obtained by the dual-curing condition without TiO₂-nt additive (DCT), which would justify the use of TiO₂-nt additives in clinical situations that rely exclusively on chemical polymerization such as the cementation of fiber-reinforced posts in root canals. It should be noted that the results of this study demonstrate that the relationship between the addition of TiO₂-nt and DC is not straightforward, which means that the increase of the concentration of TiO₂-nt do not necessarily promotes greater DC values. This result can be justified by the fact that the addition of 0.6% promotes an agglomeration of nanotubes [10] resulting in links attached to other already polymerized monomer and preventing new connections among them [26]. On the other hand, when 0.9% was added, the reaction might have been so fast that agglomeration of nanotubes may have been smaller and did not affect the link of monomers.

Even with acceptable values of DC in the dual-curing mode, with the addition of 0.3% TiO₂-nt the values increased 16%. Most likely, the insertion of this percentage allowed the cement to stay more reactive to new connections between monomers remaining in equilibrium with the polymer network that was forming. Increasing concentrations (0.6 and 0.9%) of TiO₂-nt, however, showed an average increase of only 10%, likely due to the rapid increase in viscosity generated by the conversion of the monomers.

The increase of the DC with the addition of TiO₂-nt to the cement shows an inducer potential, with the nanotubes possibly acting as a reaction coinitiator and contributing to the increase of strong crosslinked points formed in the polymeric network [10]. This is because at the nanoscale, in particular

at <50 nm, exists a confinement effect of electron pairs that results in an increase of energy between the valence band and the band gap of the material [27]. This energy is expressed chemically as a free radical (HO[•]) [10] that likely provides additional site links between the monomers.

The addition of TiO₂-nt and the polymerization condition did not influence the WS and SL of the self-adhesive resin cement. According to ISO 4049 [21], the value of clinically acceptable WS for polymeric materials is limited to 40 µg/mm³ and the SL is less than 7.5 µg/mm³. The results found in this study for WS (from 36.19 to 38.47 µg/mm³) are in accordance with the ISO's recommendations, but SL (7.66–8.14 µg/mm³) was above the values stipulated as ideal. This fact was elucidated once the resin-based materials containing acid functional monomers, such as carboxyl groups or phosphate, are significantly more hydrophilic than the materials without functional monomers, which contain only conventional TEGDMA and BIS-GMA [28,29] and are therefore more prone to WS and SL [30]. The amount of inorganic particles [31] and the nature of the bonds between the particles and the organic matrix are important [32] because the diffusion of water between the particles can occur [33]. Furthermore the cement in this study did not react with the calcium of dentin substrate, that promotes additional chemical bond and collaborate with the polymerization process [3], since it accelerates the neutralization of the low pH of the cement [34].

Some residual unpolymerized monomers may leach into the oral cavity, but most remain trapped in the already polymerized cement [30]. Those that are released into the environment can cause adverse biological reactions, penetrating the dentin tubules and pulp [35]. Those that are stuck in cement reduce the clinical longevity of the material and undergo oxidation and hydrolytic degradation, as evidenced by discoloration of the cementation of the margins [36]. This condition is directly related to the cytotoxicity of the cement, which is another important factor to be analyzed. In the current study, the indirect fibroblast viability was assessed using a MTT and Crystal Violet assay. The results showed that the incorporation of TiO₂-nt at 24, 48 and 72 h were the same for the CP group, indicating that the addition did not affect cell viability *in vitro* during these periods for the dual-curing condition. However, the DCT group at 24 h showed a significant difference in cell viability when compared to CP. This result can be explained by the relationship between the type of polymerization employed and the DC obtained with regard to the cytotoxicity of resin cements [37]. The cements with lower DC showed a significant decrease in cell survival when compared to cements with the highest DC [38].

The σ_f values obtained in this study showed that the presence of TiO₂-nt influenced the results. The inclusion of 0.3 and 0.9% of TiO₂-nt increased the σ_f value in the self-curing condition (S03 and S09) and is similar to the average value of DCT. The linear relationship between the increased amount of inserted nanotubes and an increase in strength was not observed. This may be associated with the higher conversion of monomers to concentrations of 0.3% and 0.9% in the same polymerization condition because they are properties which have a direct relationship [39,40]. For the dual-curing condition, the inclusion of 0.6% of TiO₂-nt decreased the σ_f value compared to the control (DCT), as already noted for the DC.

The inclusion of this concentration could have generated the agglomeration of nanometric particles (nanocluster), decreasing the strength of the material. The presence of defects, inclusions or pores has a negative effect on the strength of a material to act as a stress concentrator [41]. The E values obtained for the TiO₂-nt-added resin cements cured in self-curing mode (1.9–6.8 GPa) are numerically smaller than with in the dual-curing mode (4.8–7.9 GPa) [6]. The same result was found for the DCT group compared to SCT. This can occur because the characterization of the E of the development is based on the changes from an initially viscous cement to a solid material [19]. The addition of TiO₂-nt did not change the E for the dual-curing group, but the addition of 0.9% in the self-curing group (S09—1.71 GPa) resulted in values similar to those of the dual-curing groups. This increase can be explained by the fact that the E of the material can be changed depending on the inorganic composition [42,43]. It has been suggested that a desirable E value for a cementing agent should be between the value of the indirect restoration and the mineralized tooth structure (12–14 GPa to dentin and 46–48 GPa enamel [44]), which contributes to reducing stress concentrations at the interface [45] and consequently leads to the reduction of marginal gaps [46].

With the addition of 0.6% and 0.9%, independent of polymerization conditions, the microhardness results were significantly higher when compared to the control groups. In other studies [10], at a certain concentration, the addition of TiO₂-nt leads to a decline in hardness, but discrepancies between methods to evaluate hardness and the material itself are observed. The Knoop indenter is the most suitable for the hardness analysis of polymeric materials [44], and the indenter application site may interfere in the results. This is because in the central region of the specimen, free radicals are dimensionally more exposed compared to located at the ends [47]. Moreover, the high surface area of the hollow nanotube structure allows a resin matrix interlock with the inner and outer surfaces of the tubes, acting to strengthen the structure and resulting in a material with improved mechanical properties [11].

The increase of DC values of the reinforced cement influenced most of the other properties studied, as found in other studies [37,38,48]. In a general analysis, the addition of TiO₂-nt in the evaluated self-adhesive resin cement positively influenced its properties, especially in the self-curing mode, which has an indication for use with certain limitations. There was no consensus on the results as to the optimal concentration to improve all properties evaluated. However, the inclusion of 0.3 wt% to 0.9 wt% TiO₂-nt was responsible for the most favorable results in the study.

The lack of equality in the results could be improved by the functionalization of nanotubes, one of limitations of this study, once the nanoscale structures tend to agglomerate, decreasing their dispersion into the material [11]. Other limitations as the understanding the real chemical interaction of TiO₂-nt and resin monomers and the absence of dentin tissue that have an important role in the neutralizing reaction of self-adhesive resin cement are important factors to be discussed in later studies to allow its feasibility of use in the future.

5. Conclusions

The addition of TiO₂-nt addition to self-adhesive resin cement had an influence on the DC, flexural strength, elastic modulus, microhardness and indirect fibroblast cell viability. It is possible to considerably increase the DC of the self-adhesive resin cement 15 min after handling when used in the self-curing condition by adding 0.3 wt% to 0.9 wt% of TiO₂-nt.

The mechanical properties of the self-adhesive resin cement (σ_f , E and hardness) were influenced by the presence of TiO₂-nt. Indirect cell viability of TiO₂-nt-reinforced cement was the same for the CP group and did not result in toxicity among the time tested.
