ARTICLE INFO

ABSTRACT

We report herein an investigation on the ozone gas-sensing performance at room temperature of SnO$_2$ nanoparticles assisted by a light-emitting diode. X-ray diffraction and high-resolution transmission electron microscopy analyses indicated the nanocrystalline characteristics of the SnO$_2$ particles after heat treatment. Besides, optical measurements pointed out that the nanoparticles presented an optical gap of approximately 3.8 eV with a broad photoluminescence emission at around 625 nm, which was linked to the presence of oxygen vacancies, suggested by XPS analysis. With regard to the light-assisted gas-sensing measurements, electrical analysis revealed a clear dependence of the ozone sensing performance on the wavelength of the source of illumination chosen, with the highest ozone response being reached upon excitation in the ultraviolet region. Theoretical calculations showed that the (110) surface could increase the stability of photogenerated carriers and contribute to enhancing the gas-sensing features under ultraviolet excitation due to the presence of [SnO$_6$] and [SnO$_5$] clusters, which are capable of inducing an electron-hole dissociation and a reliable chemical environment for O$_3$ interaction.

1. Introduction

Metal semiconducting oxides (MOXs) have attracted growing attention due to their potential in diverse practical applications, including resistive gas sensors. [1–5] With regard to resistive gas sensors or chemiresistors, they have been investigated for the detection of various analytes, mainly harmful species, such as NO$_x$, CO, NH$_3$, H$_2$S, and O$_3$. [1,6–9] According to the literature, chemiresistors based on MOXs have worked at relatively high temperatures, i.e., superior to 150 °C. To achieve such temperatures, self-heaters have been made up in the structure of the device, thus involving more complexity in the manufacturing steps, besides increasing the energy consumption of the such devices. [10–12] Note that these operating temperatures may provoke permanent changes in the chemical and structural characteristics of the sensing layer, impairing its lifetime. [13,14]

In this sense, researchers have focused on the development of sensing materials with high sensitivity and selectivity, and fair stability, apart from operating at moderate temperatures (preferably close to room temperature). An efficient and versatile strategy to achieve sensitivity has been the full or partial replacement of the conventional thermal activation by light stimulation. [10,11,15–17] The irradiation of the sensing materials with a low-energy consumption source such as light-emitting diodes (LEDs) has provided promising results. In previous works, we reported that the ozone gas-sensing properties of ZnO-SnO$_2$ nanocomposites and pristine ZnO were improved when the materials were kept under continuous UV illumination. [15,18] In another study, Gonzalez et al. combined thermal and light stimulations to enhance the sensing performance of WO$_3$ nanoneedles. [11,19] They reported that the combination of mild heating ($\leq$ 100°C) with pulsed UV light irradiation of the sensing layer resulted in a significant increase in the sensing activity of the WO$_3$. [19]

Among the various MOXs investigated as light-assisted sensing materials, tin dioxide (SnO$_2$) has been applied for the detection of a wide range of analytes. [20–22] In its stoichiometric form, this compound acts as an insulator, while the SnO$_{2-\delta}$ behaves as an n-type semiconductor with a band gap of approximately 3.6 eV at 300 K. [23] The

presence of such defects in the SnO$_2$ network, e.g. oxygen vacancies, has allowed the use of wavelength in the visible region to stimulate its gas-sensing properties at room temperature. [24–29] For example, Anothainart et al. reported the NO$_2$ sensing properties of the SnO$_2$ compound under visible illumination at room temperature. [24] They observed that the photoexcitation with wavelengths smaller than 600 nm was enough to activate the adsorption mechanism of SnO$_2$. Despite the fact that ozone gas sensors based on SnO$_2$ compound are widely studied, few papers have specifically studied of the effect of wavelength on the light-assisted ozone sensing performance of SnO$_2$. Motivated by these considerations, we investigate herein the role played by the different wavelengths employed to assist the ozone gas sensing experiments using SnO$_2$ nanoparticles as a sensing layer. For this purpose, experimental and theoretical approaches were employed in order to evaluate the SnO$_2$ sensing activity. X-ray diffraction, transmission electron microscopy, optical spectroscopies, and electrical measurements were performed along with first-principles calculations to get insight into the electronic properties of adsorption of O$_3$ molecules on the SnO$_2$ surfaces.

2. Experimental section

2.1. 2.1. Synthesis of SnO$_2$ nanoparticles

The SnO$_2$ nanoparticles were synthesized via hydrolysis of tin chloride, followed by thermal treatment. The tin (II) chloride (SnCl$_2$.6H$_2$O, 99.9%) and ethyl alcohol anhydrous (CH$_3$CH$_2$OH, 99.5%) were purchased from Sigma-Aldrich Corporation and used without any further purification. The tin chloride (0.1 M) was dissolved in 100 mL of ethyl alcohol under constant stirring at room temperature. Then, 22.5 mL of deionized water was dropped into the solution, which was kept under stirring for 30 min. To remove the chlorides from the solution, the dialysis process was performed, and the obtained precipitate was dried in an electric oven at 80 °C overnight. The as-obtained powder had an amorphous characteristic, revealed by X-ray diffraction analysis. To obtain a crystalline sample, it was annealed in an electric oven for 1 h at 500°C under an air atmosphere.

2.2. 2.2. Characterization techniques

X-ray diffraction measurements were collected using a Shimadzu diffractometer (XRD6100, CuKα radiation) in the 2θ range from 20° to 80° with a step of 0.02, and at scanning speed of 2° min^{-1}. Ultraviolet-visible diffuse reflectance spectrum (UV-vis DRS) was collected on a spectrophotometer (Shimadzu, UV-2600) coupled to an integrating sphere from 200 to 800 nm. The morphological features were investigated using a high-resolution transmission electron microscopy (HRTEM, FEI Tecnai G2 F20) operating at 200 KeV. Room temperature photoluminescence (PL) measurements were performed using a 355 nm laser as the excitation source, focused on a 200 μm spot at constant power of 5 mW. The luminescence signal was dispersed by a 19.3 cm spectrometer (Andor/Kymera) and detected by a Si charge-coupled device (Andor/Idus BU2).

2.3. 2.3. Gas-sensing experiments

To perform the ozone gas-sensing measurements, the sensors were prepared following a procedure commonly adopted by our team [15, 30–32]. First, 50 mg of the sample was dispersed in 0.5 mL of isopropyl alcohol using an ultrasonic cleaner. The obtained suspension was then dripped onto a SiO$_2$/Si substrate with 120 nm thick Pt electrodes separated by a distance of 50 mm. To remove the solvents in the suspension, the sensor sample was annealed for 30 min at 500°C in an electric oven. Afterwards, the sensor sample was inserted into a special chamber that allows the control of the substrate temperature, the gas flow, and the O$_3$ levels. The O$_3$ gas was generated using a calibrated

pen-ray UV lamp, providing concentrations ranging from 12 to 94 ppb. In these dynamic experiments, the dry air (carrier gas) containing O$_3$ gas was blown directly onto the sample, keeping a constant flux of 500 SCCM. Further details regarding the gas-sensing workbench may be found in our previous works. [30,31,33,34] The electrical resistance of the sample was monitored with an electrometer (Keithley, 6514) by applying a voltage of 1 V (*DC*). All measurements were carried out at room temperature (25 ± 1 °C) under continuous light irradiation provided by a light-emitting diode (LED) 10 mm distant from the sensing sample. The wavelengths studied here were UV (315 nm, 0.6 mW), violet (405 nm, 10 mW), and blue (465 nm, 20 mW). Longer wavelengths were also investigated, however, no influence on the sensing performance was found. It is worth mentioning that for each experiment using a certain LED, the studied sample was kept in a dark chamber overnight to protect it from any previous light stimulation. The sensor response (S) was defined as S=R$_{O3}$/R$_{air}$, where R$_{O3}$ and R$_{air}$ are the electric resistance of the sensor exposed to O$_3$ gas and dry air, respectively. [15,31,32]

2.4. 2.4. Computational methods

Theoretical calculations based on the Density Functional Theory were carried out by combining hybrid B3LYP [35,36] functional and two- and three-body contributions to the long-range dispersion energy (B3LYP-D3), [37] as implemented in the CRYSTAL17 code. [38] Herein, bulk and surface models were used to investigate the O$_3$ gas sensing properties of SnO$_2$. The tetragonal rutile phase was generated from XRD data, while the non-polar (100) and (110) surfaces were constructed using symmetrical and stoichiometric slabs. Durand–Barthelat (DB) core pseudopotentials were used for Sn atoms [Kr]5s25p2, whereas O centers were described with all-electron 6-31G* basis set, following previous theoretical studies for bulk and surface SnO$_2$ models. [39–41] The electronic integration over the Brillouin Zone was performed using a 8 × 8 × 8Monkhorst–Pack k-mesh. [42] Five thresholds were set to 8, 8, 8, 8, and 16 in order to control the accuracy of the Coulomb and exchange integral calculations. The convergence criteria for mono and bielectronic integrals were set to 10^{-8} Hartree, while the RMS gradient, RMS displacement, maximum gradient, and maximum displacement were set to 3 × 10^{-4}, 1.2 × 10^{-3}, 4.5 × 10^{-4} and 1.8 × 10^{-3} a.u., respectively. The electronic properties were evaluated through the density of states (DOS), band structure profiles, and charge analysis tools implemented in the CRYSTAL17 code. [38]

Aiming to investigate the O$_3$ sensing properties of the SnO$_2$ samples, adsorption models were constructed from (2 × 2) supercell expansions of previously optimized slabs. The adsorption enthalpy was calculated considering the expressions:

$$E_{ads} = \frac{1}{N}\left[E_{(slab+O_3)} - \left(E_{slab} + NE_{O_3}\right) + E_{BSSE}\right] \qquad (1)$$

$$E_{BSSE} = \left(E_{slab}^{frozen} - E_{slab+ghpst}^{frozen}\right) + \left(E_{O_3}^{frozen} - E_{O_3+ghpst}^{frozen}\right) \qquad (2)$$

here $E_{(slab+O_3)}$ is the total energy of the optimized slab with adsorbed O$_3$ molecule, E_{slab} is the total energy of the isolated optimized slab, N is the number of adsorbed O$_3$ molecules per unit cell and E_{O3} is the total energy of ozone in the gas phase. The basis set superposition error (BSSE) was calculated considering the two separated moieties (slab + O$_3$) frozen in the minimum adsorption configuration, with and without ghost functions, respectively.

The photo-assisted O$_3$ sensing properties were evaluated considering the existence of excited electrons and holes through the localization of charge doping levels using the keyword DOPING, which allows adding (or removing) electrons to (from) the system. [38]

3. Results and Discussions

X-ray diffraction (XRD) patterns of the SnO$_2$ samples before and after
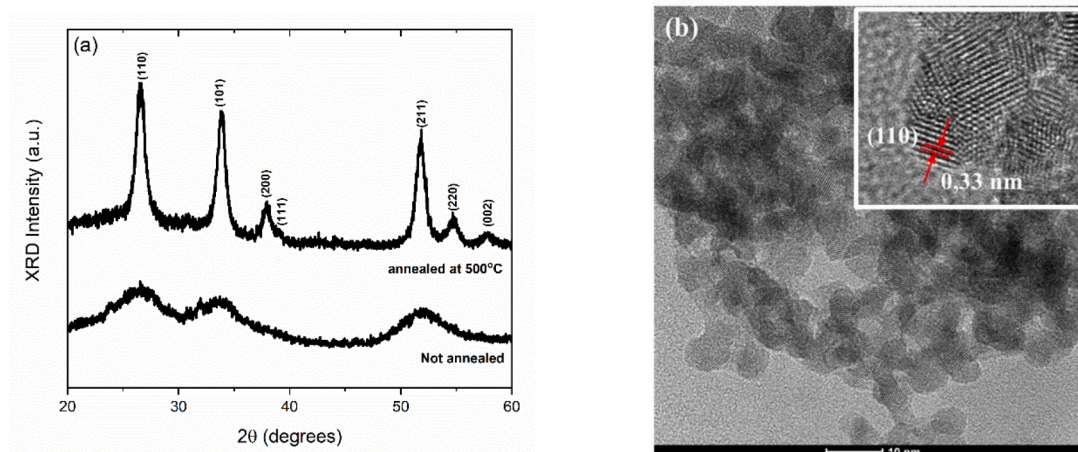

Fig. 1. (a) XRD patterns of SnO$_2$ samples before and after heat treatment. (b) HRTEM micrograph of the annealed sample. The inset in Fig.(b) shows the interplanar distance of the nanocrystalline SnO$_2$ sample.
Fig. 2. Optimized crystalline structures for SnO$_2$ bulk and surface models.

heat treatment are displayed in **Fig. 1(a)**. It can be seen that the as-obtained sample presents a typical amorphous XRD pattern and, after the annealing process XRD peaks were observed. These XRD reflections confirm that the crystalline structure was obtained. Additionally, they match the tetragonal rutile phase of SnO$_2$, according to Joint Committee on Powder Diffraction Standards (file #36-1451). With regard to the

morphological features, **Fig. 1(b)** shows an HRTEM micrograph of the crystalline SnO$_2$ sample. An analysis of this image reveals that the nanometric characteristic of the particles remains with an average size of 6 nm even after heat treatment. Moreover, the inset in **Fig. 1(b)** presents the interplanar distance of (110) crystallographic plane of the SnO$_2$ phase, which is approximately 0.33 nm. [43,44]

Theoretical results for bulk and surface models of SnO$_2$ are summarized in **Fig. 2**, indicating the building blocks that describe the crystalline structure. It can be seen that the calculated lattice parameters for SnO$_2$ were $a = b = 4.664$ Å and $c = 3.155$ Å, which are in accordance with previous theoretical and experimental results. [39–41] The building block of SnO$_2$ is the [SnO$_6$] cluster, which is composed of two short (2.018 Å) and four long (2.031 Å) Sn-O bonds. For the (100) and (110) surface models, the existence of a single dangling bond forming under-coordinated [SnO$_5$] centers can be noted. The significant difference between the surface models can be attributed to the [SnO$_5$] orientation and the presence of superficial [SnO$_6$] clusters along the (110) surface, inducing increased stability for the latter.

The optical absorbance measurement of the SnO$_2$ nanoparticles is displayed in **Fig. 3**, black curve. The optical band gap (E$_g$) values of both samples were determined using the Kubelka-Munk equation,[45] which provided a value of approximately 3.4 eV. This value is in accordance with that reported literature for the SnO$_2$ compound.[46,47]. Furthermore, an analysis of the SnO$_2$ spectrum (black curve, **Fig. 3**) reveals the existence of a tail extending close to around 2.8 eV, indicating the presence of intrinsic defects, mainly oxygen vacancies, capable of creating new electronic levels within the band gap. [48,49] In the same figure, (blue curve, **Fig. 3**), it is possible to observe that the photoluminescence (PL) spectrum of the SnO$_2$ nanoparticles consists of a broad emission band whose maximum is located at around 625 nm. According to the literature, the presence of such intermediate levels leads to a system in which the relaxation process happens by several
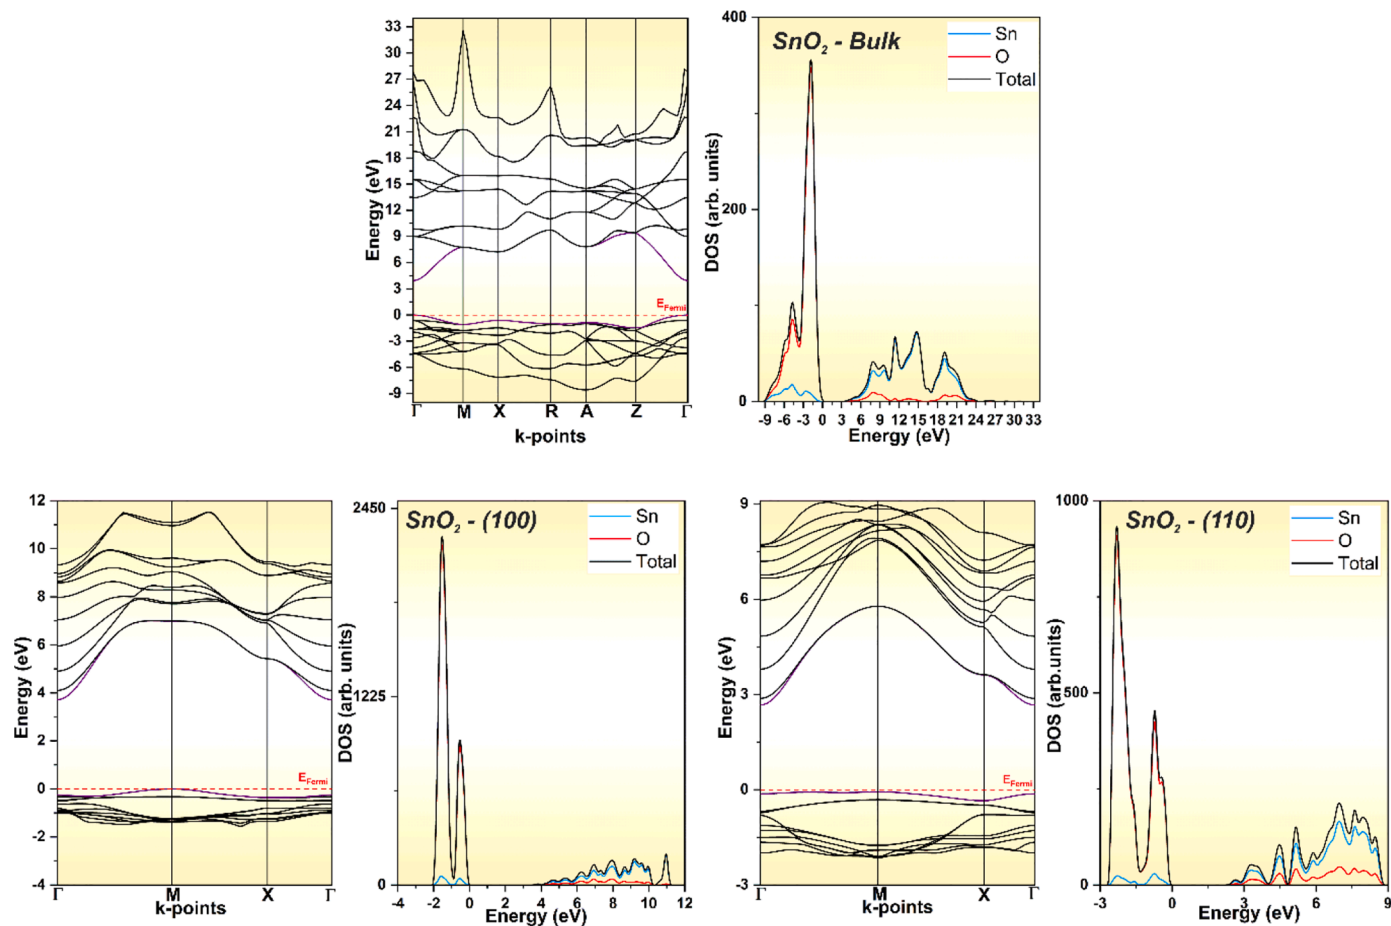

Fig. 4. Band Structure and atom-resolved Density of States profiles calculated for SnO_2 bulk and surface models.

paths, thus originating a broad emission band. [50,51]. Bonu et al. reported that the PL emission around 625 nm can be attributed to defects created by oxygen vacancies in the SnO_2 lattice. [44] Similarly, Kar et al. conducted a detailed experimental investigation on the PL properties of SnO_2 nanorods and nanoparticles. [52] According to their findings, the PL emission can be linked to a transition of an electron from a level close to the conduction band edge to a deeply trapped hole in the bulk. [52] Therefore, the presence of such oxygen vacancies (here suggested by XPS analysis, Fig.S1) contribute to the formation of new levels in the band gap region of the SnO_2, enabling that longer excitation wavelengths generate charge carriers in the sensing layer. [15,53].

Regarding the electronic properties of SnO_2, DFT calculations were carried out for both bulk and surface models to describe the bandgap region. For the bulk model (central panel of Fig. 4), it can be observed that the valence band is mainly composed of O (2p) states, while the conduction band is formed by Sn (5sp) states. The electronic band gap was calculated as a direct transition equal to 3.92 eV, which is close to the obtained experimental results. The electronic states distribution remains equal for the (100) and (110) surface models, whilst the electronic band gap reduces to 3.72 and 2.67 eV, respectively. The band gap narrowing can be associated with the chemical environment of the exposed surfaces, i.e., the undercoordinated Sn centers induce the creation of intermediary states that contribute to reducing the required energy for electronic excitation.

The ozone gas-sensing properties of the nanocrystalline SnO_2 sample was studied under continuous illumination using certain excitation wavelengths, i.e., UV, violet and blue. Note that the sample was also exposed to ozone gas in a dark mode to verify the effect of illumination . Fig. 5(a) shows the response of the SnO_2 nanoparticles exposed to 12 ppb of O_3 in the absence of any light stimulation (dark mode). As

observed, the sensing activity is apparently null, however, a closer view reveals a very low response, beyond the non-desorption of the O_3 molecules. It means that this configuration (dark mode and room temperature) did not provide enough energy to get an efficient desorption of the O_3 molecules from the sensing surface.

To evaluate the effect of light stimulation on the ozone gas-sensing performance, the sample was then submitted to different ozone levels (Fig. 5(b)-(d)). These measurements were performed at room-temperature, keeping the sample under continuous illumination stimulation and, only varying the wavelength of light source.

For the three distinct wavelengths studied, the sample presented sensing activity when exposed to different O_3 levels, always achieving full recovery after each exposure cycle. From the analysis of Fig. 5, it is evident that the employment of a certain wavelength to assist in the sensing process affects considerably the adsorption and desorption processes. These findings suggest that the energy of the photons provided by the light source may be used to tune the ozone sensing performance of SnO_2 nanoparticles.

Fig. 6(a) displays the sensor response curve of the nanocrystalline SnO_2 sample exposed to different ozone levels when irradiated by different light sources (UV, violet and blue). These data were extracted from Fig. 5, and show an enhancement of the sensor response with increasing ozone level for all light sources here investigated. In fact, Fig. 6(a) confirms that the sensor response depends on the wavelength chosen to perform the light-assisted sensing measurements. The observed order of gas-sensing performance is UV > violet > blue. Note that for the lowest analyte concentration (12 ppb) the wavelength chosen did not affect the sample response, indicating low accuracy of the sample for very low ozone levels.

Regarding the wavelength of the light source employed in the
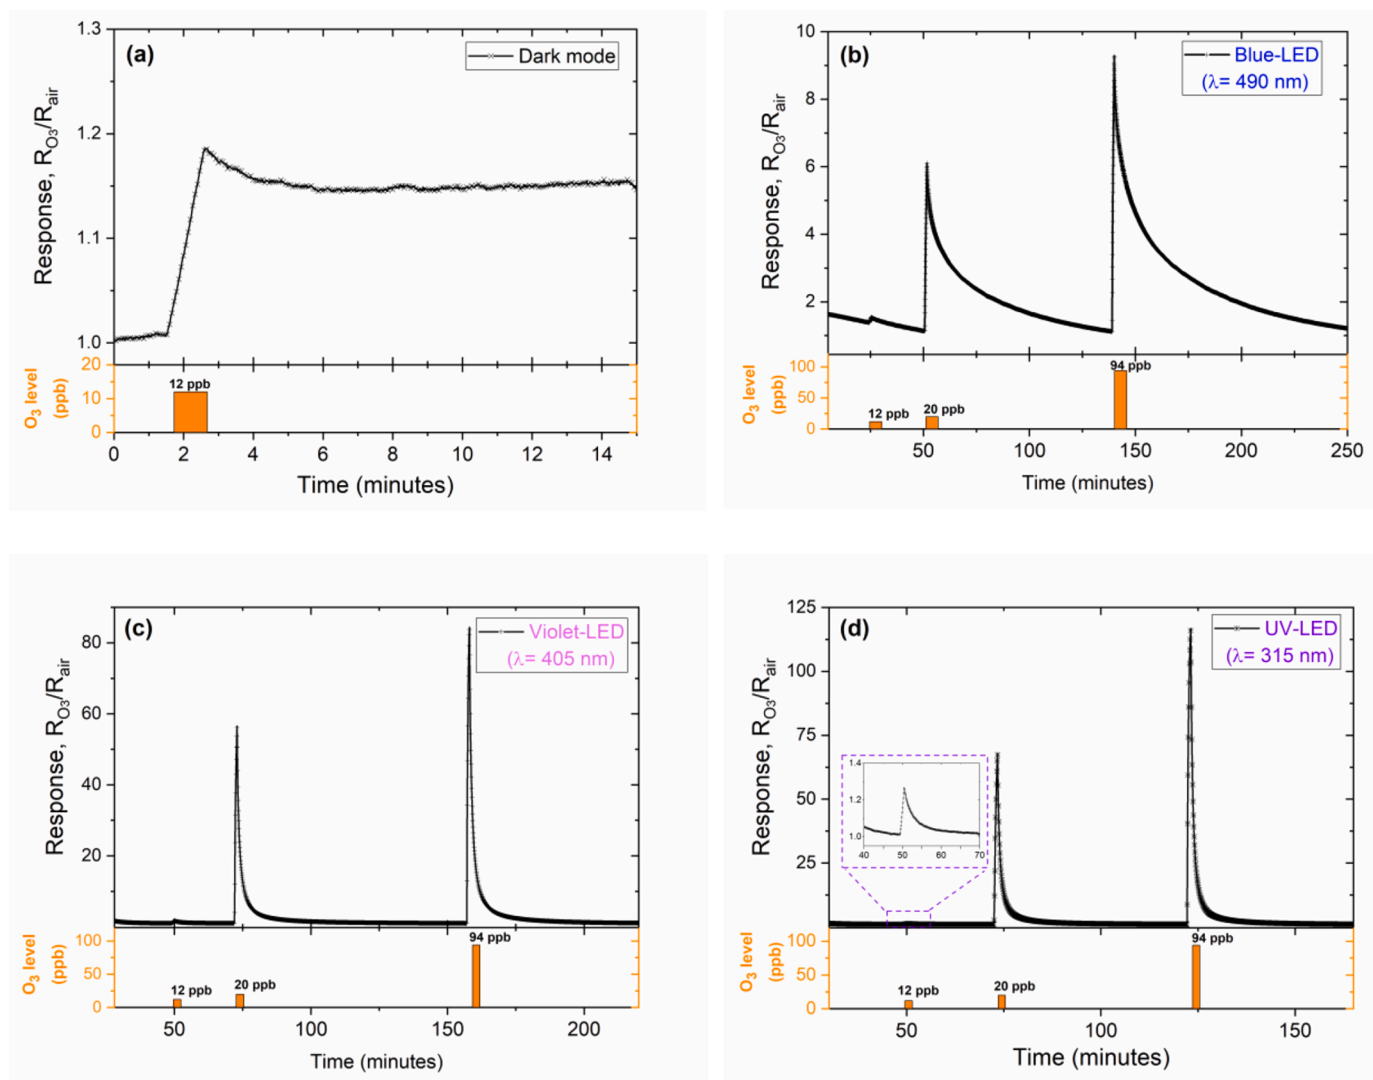

Fig. 5. Room-temperature gas sensing response of nanocrystalline SnO_2 sample exposed to different O_3 levels (12, 20, 94 ppb) and continuously assisted by a light source. (a) without any illumination "dark mode", (b) blue, (c) violet, and (e) UV-light.

sensing experiments, the UV source has been widely explored. [10,11, 15,53] Its choice is based on the band gap energy of the sensing material. However, as previously discussed the presence of different defects in the nanocrystalline SnO_2 makes wavelengths in the visible region useful for assisting ozone gas-sensing measurements. It can be seen in **Fig. 6(b)** that the ozone sensing response depends on the wavelength of the light source used to assist the SnO_2 sample. It is noteworthy that the sample detected the O_3 gas (presenting total recovery) when illuminated by the following wavelengths: UV, violet and blue, with no sensing activity when irradiated by green light. An analysis of the curve presented in **Fig. 6(b)** reveals a significant reduction in the sensor response at longer wavelengths, demonstrating the importance of photogenerated charge carriers in the detection of O_3 molecules.

Table 1 presents the performance of some MOXs synthesized by different methodologies, applied as a light-assisted ozone gas sensing material. It can be seen, the minimum ozone level detected by SnO_2 nanoparticles is close to those reported for other MOXs. It demonstrated that the chemical synthesis here used is a facile method to prepare efficient ozone gas sensors.

Let us now analyze the ozone gas-sensing properties of SnO_2 and their relationship with light activation. For this purpose, the first analysis involves the electron and hole localization and the exposed (100) and (110) surfaces modeled from the addition and removal of electrons

from previously optimized surfaces, as depicted in **Fig. 7**. The excited electron is localized on the undercoordinated [SnO_5] cluster for both surfaces, while the hole is localized on the neighboring oxygen atoms. The significant difference is related to the hole localization. For the (100) surface, the hole is localized on the superficial oxygen atoms, i. e., the [SnO_5] is directly involved in the electron-hole excitation and localization.

On the other hand, for the (110) surface the hole is localized on the neighboring [SnO_6] cluster, reducing the probability of electron-hole recombination, and consequently increasing the reactivity. This fact follows the structural and electronic features reported above, where the existence of both [SnO_5] and [SnO_6] surfaces induce higher surface stability and increased reactivity despite the increased band gap value in comparison to the (100) surface. Therefore, even though the narrow band gap of the (100) surface induces an increased rate of electron-hole excitation using the visible spectra region (2.64 eV = 464.36 nm), the localization of excited charge carriers reduces the stability and increase the recombination rate in comparison to (110). In this context, it is possible to argue that the SnO_2 (110) surfaces are better for UV-assisted gas adsorption since the charge carriers remain stable.

In order to evaluate the gas-sensing property of the SnO_2 surfaces, the adsorption energy of O_3 was calculated considering neutral and charged surface models. The major structural features evaluated to
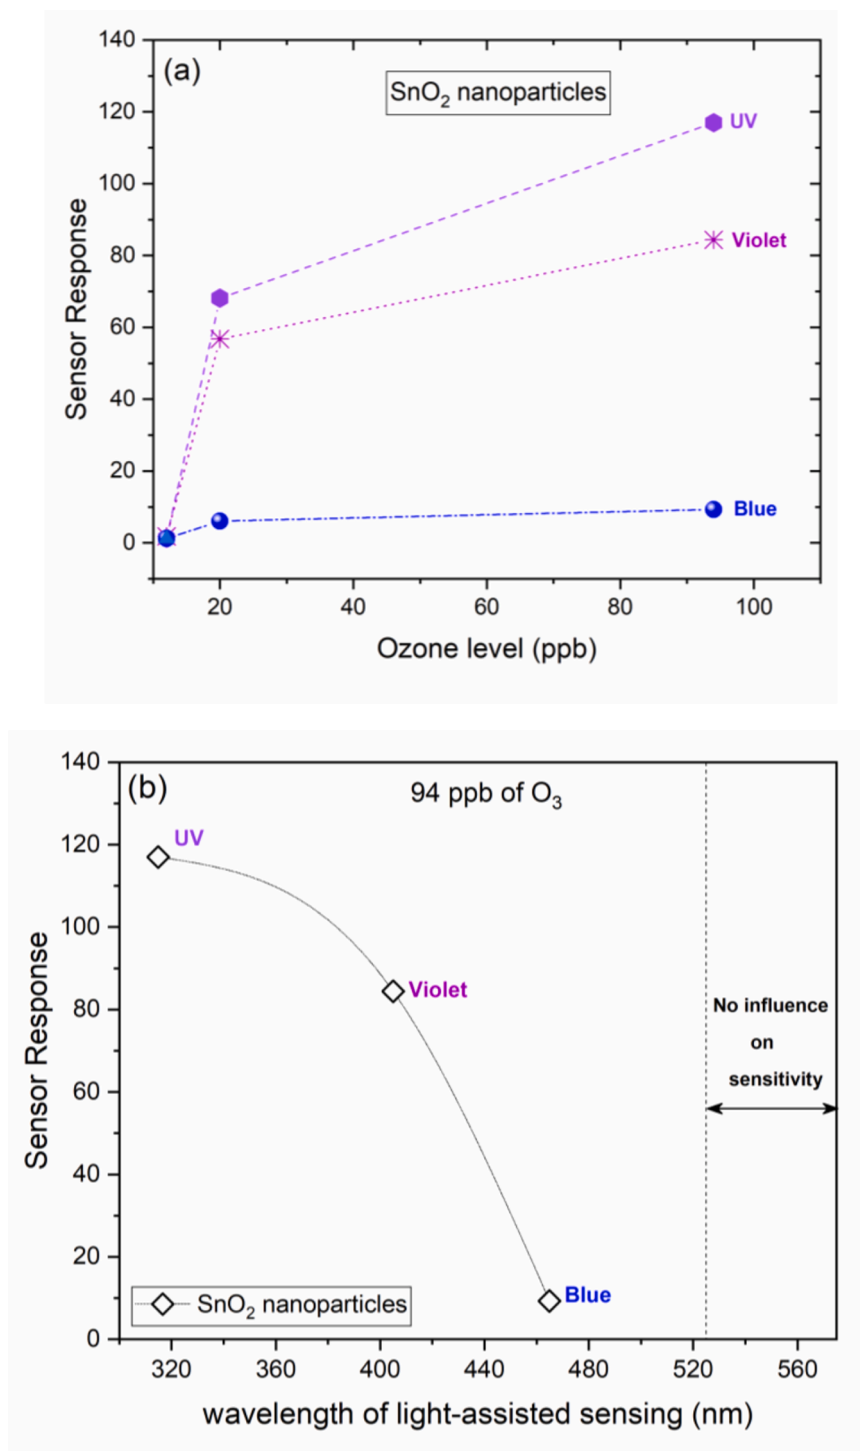

Fig. 6. Light-assisted ozone sensing response of nanocrystalline SnO$_2$ sample as a function of (a) ozone level and, (b) wavelength of light-assisted.

investigate the O$_3$ gas-sensing properties before and after electronic excitation are depicted in **Fig. 8** and summarized in **Table 2**.

First, it can be observed that the O$_3$ adsorption occurs as two-point interactions for the (100) surface and one-point interaction for the (110) plane, resulting in superior adsorption energy for the former. Moreover, the distance between the O$_3$ molecule and the under-coordinated Sn center is smaller for the (100) surface, indicating that the neighboring [SnO$_5$] clusters contribute to induce a superior geometrical orientation that governs the adsorption mechanism. Furthermore, the ozone adsorption along both SnO$_2$ surfaces maintains the molecular geometry for O$_3$, indicating a reversible mechanism.

The most critical features analyzed from **Table 2** are associated with the geometrical constraints resulting from the localization of excited electrons and holes. For the (100) surface, the localization of missing electrons (holes) points to a minor reduction of Sn-O$_3$ bond length, indicating that the adsorption energy does not increase with the hole localization. However, after the localization of adding charges (electrons), the Sn-O$_3$ distances reduce to a greater extent, demonstrating that excited electrons enhance the O$_3$ adsorption mechanism. These facts are related to the localization of electronic states reported in atom-resolved DOS (Fig. S3), where the obtained results for O$_3$ adsorption after electron localization suggests a different pattern associated with

the contribution of Sn centers, while the hole localization spreads out along all oxygen atoms of the exposed surface.

On the other hand, for the (110) surface the calculated Sn-O_3 bond distances after the localization of electrons and holes reduce almost by the same extent, indicating that both mechanisms increase the adsorption energy and O_3 gas-sensing properties. Such fact can be attributed to the presence of both [SnO_5] and [SnO_6] clusters along the exposed

Table 2
Adsorption energy (E_{ads}) and structural parameters evaluated for O_3 adsorption along with the (100) and (110) surface models of SnO_2. The oxidized (+1) and reduced (-1) refer to the localization of missing and adding electrons, respectively.

Surface	Electronic state	E_{ads}(ev)	^{1}O-O (Å)	Θ	^{2}Sn-O (Å)
(100)	Neutral	-0.75	1.275	119.04	2.400
	Oxidized (+1)	-	1.269	119.68	2.389
	Reduced (-1)	-	1.343	121.66	2.185
(110)	Neutral	-0.33	1.261	119.79	2.546
	Oxidized (+1)	-	1.264	121.15	2.432
	Reduced (-1)	-	1.302	117.53	2.456

surface, which contribute to the localization of excited charge carriers in different crystalline sites, enhancing the O_3 adsorption mechanism for both electronic states, as presented in atom-resolved DOS (**Fig. S3**).

As previously discussed, the (110) surface exhibits an increased charge carrier stability since the electrons and holes are localized in distinct clusters, resulting in a reduced recombination rate. Therefore, the UV-assisted excitation generates photoexcited charges responsible for enhancing the O_3 sensing performance. In contrast, despite the band gap reduction (visible spectra) and increased adsorption energy for the (100) surface, the excited charge carriers exhibit a more effective recombination rate, which in turn reduces the O_3 sensing activity.

4. Conclusions

In summary, the pristine SnO_2 compound operating at room temperature under continuous light stimulation was investigated as an ozone gas sensor. XRD and HRTEM analyses confirmed the nanocrystalline characteristics of the sample after heat treatment. Electrical measurements revealed a dependence of ozone sensing performance on the wavelength of light stimulation. The maximum ozone response of the SnO_2 nanoparticles was reached under UV light, while no sensing activity was observed for light stimulation using a green light source. The DFT calculations used to support the experimental measurements showed the significant aspects associated with the stability of photo-generated carriers along the (100) and (110) surfaces of SnO_2 and confirmed that the presence of undercoordinated and regular Sn centers contributed to exciton dissociation on the (110) surface and increased adsorption energy after electronic excitation. We believe that the findings presented herein may be extended for further light-assisted sensing materials, such as ZnO, WO_3, and In_2O_3.
